Development of a Nano-Alumina-Zirconia Composite Catalyst as an Active Thin Film in Biodiesel Production

N. Marzban, J. K. Heydarzadeh, M. Pourmohammadbagher, M. H. Hatami, A. Samia

Abstract—A nano-alumina-zirconia composite catalyst was synthesized by a simple aqueous sol-gel method using AlCl₃·6H₂O and ZrCl₄ as precursors. Thermal decomposition of the precursor and subsequent formation of γ-Al₂O₃ and t-Zr were investigated by thermal analysis. XRD analysis showed that γ-Al₂O₃ and t-ZrO₂ phases were formed at 700 °C. FT-IR analysis also indicated that the phase transition to γ-Al₂O₃ occurred in corroboration with X-ray studies. TEM analysis of the calcined powder revealed that spherical particles were in the range of 8-12 nm. The nano-alumina-zirconia composite particles were mesoporous and uniformly distributed in their crystalline phase. In order to measure the catalytic activity, esterification reaction was carried out. Biodiesel, as a renewable fuel, was formed in a continuous packed column reactor. Free fatty acid (FFA) was esterified with ethanol in a heterogeneous catalytic reactor. It was found that the synthesized γ-Al₂O₃/ZrO₂ composite had the potential to be used as a heterogeneous base catalyst for biodiesel production processes.

Keywords—Nano-alumina-zirconia, composite catalyst, thin film, biodiesel.

I. INTRODUCTION

NOWNADAYS, several catalytic reactions such as base catalyzed esterification [1]-[3], acid-catalyzed esterification [4], [5], enzymatic esterification [6], [7], and heterogeneous catalyst esterification [8], [9] are used for biodiesel production from FFAs. Now, the homogeneous catalysts are being extensively used for the production of biodiesel at industrial scale such as sulfuric acid, the most common homogeneous catalyst consumed in biodiesel synthesis [10]. The use of the homogeneous catalysts, however, has some disadvantages. One of the most obvious disadvantages of homogeneous catalysts is that they should be eliminated from the final product by repeated washing with distilled water, thereby causing the formation of a massive amount of wastewater. In order to overcome such problems, heterogeneous catalysts are applied. Heterogeneous catalysts can be easily separated from the final product and used several times. Alumina is widely used as a catalyst due to its favorable catalytic properties [11]. In particular, γ-alumina, which has large surface area and suitable pore size distribution, is an important catalyst for binding organic compounds [12].

Zirconia is one of the additives which can increase the strength and toughness of the alumina matrix either by stress-induced transformation toughening or microcrack toughening [13]. Zirconia was selected due to its chemical inertness (compared to other oxide phases), intrinsic catalytic activity (higher than other classical supports like pure Al₂O₃ or SiO₂), and the thermal stability of the Al₂O₃-ZrO₂ composite system [14], [15]. On the other hand, it was also shown that alumina delayed the crystallization, increased the specific surface area and pore volume, and enhanced the surface acidity of zirconia [16].

Several methods for the preparation of the alumina-zirconia nanopowders and composites have been reported in the literature [17]-[21]. The sol-gel process is one of the most useful techniques used to offer the possibility of making ultra-homogeneous structures and it has been widely used in the synthesis of glasses, ceramics, and composites catalysts [15], [17]. Sol-gel method is also used for preparing the gels of various shapes such as monoliths, fibers, coating films, spheres, and so on. It is well known that the composition of the starting alkoxide solution including the type of catalyst, water content, the presence or absence of any additives, and the reaction conditions directly affects the rate of hydrolysis, the rate of condensation, the shape of produced polymer particles in the solution, and the state of aggregation of particles, respectively. Thus, characteristics of the sols and gels produced in the reaction could be easily changed by varying several parameters. Sol-gel method, among different coating methods used, has shown promising results due to its low cost, simple control of the synthesized parameters, and the ability to form a uniform coating over large or complex geometric shapes physically and chemically. It has the potential to enhance physical and chemical properties due to the nanocrystalline structure of the coatings [16], [17].
Several investigators have used solutions/sols of alumina and zirconia salts or suspensions of Al$_2$O$_3$ and ZrO$_2$ powders to control the particle size of ZrO$_2$ and Al$_2$O$_3$ [20]. In this research, the sol-gel method was used to synthesize a nano-thin film of alumina-zirconia composite catalysts. Prepared samples obtained through sol-gel technique were then characterized by BET surface area, TEM, XRD, FTIR, and AFM analysis. The purpose of the present research was to develop an effective catalytic process for biodiesel production using nano-alumina-zirconia composite as an active thin film.

II. MATERIALS AND METHODS

A. Preparation of Al$_2$O$_3$/ZrO$_2$ Composite Catalyst Thin Film

In order to synthesize Al$_2$O$_3$/ZrO$_2$ nanocomposite particles, aluminum chloride hexahydrate (AlCl$_3$.6H$_2$O), zirconium (IV) chloride (ZrCl$_4$), yttrium (III) nitrate (Y(NO$_3$)$_3$.6H$_2$O), citric acid (C$_6$H$_8$O$_7$), and ethylene glycol (HOCH$_2$CH$_2$OH) were prepared by the sol-gel method. All materials were supplied by Merck (Darmstadt, Germany). Fig. 1 shows the stepwise procedures employed for the preparation of the nanocomposite particles and the thin film by the sol-gel method. The mixture of the solutions was relatively stable, i.e., no precipitation or phase separation was observed during the process.

![Fig. 1 Typical flow chart of processing nanocomposite Al$_2$O$_3$-ZrO$_2$ thin film](image)

Ceramic plates were used as the substrate material. The substrates were coated by dip-coating technique and withdrawn in the solutions at a constant speed of about 1 mm/s. The coated substrates were allowed to be dried at 70 °C for 12 h. The coated plates were then calcinated at 700 °C for 5 h.

B. Catalyst Characterizations

The morphology of the calcinated powders of the thin film was investigated by using a Philips EM208S transmission electron microscope (TEM). The phase analysis of the thin film was carried out by an Auto Probe model CP atomic force microscope (AFM, Park scientific instruments, USA) using a Si$_3$N$_4$ probe.

C. Reaction Test

The esterification process was carried out in a continuous packed bed reactor. The column was packed and loaded with palletized catalysts (600 g, γ-Al$_2$O$_3$/ZrO$_2$). About 82% of the reactor volume was occupied by the palletized catalysts. The schematic diagram for the experimental setup is shown in Fig. 2. Fatty acids mixture and ethanol were primarily heated up to 50 °C in a mixing tank. The fatty acids were pumped to the top of the column. The FFA met and interacted with ethanol on the active sites of catalysts, and the ester product was instantaneously formed. The product was transferred to a flash drum separator [22].

III. RESULTS AND DISCUSSION

A transmission electron microscope (TEM) was used to analyze the particle size and morphology of the nanocomposite powder particles. Fig. 3 shows the micrograph of alumina-zirconia composite powders synthesized using sol gel method and calcined at 700 °C for 5 h. Most particles were in the range of 10-15 nm. The phenomenon of meso-porosity within

\[

\]

where D is the crystalline size (nm), λ is the wavelength of X-ray radiation (1.54056 Å), θ is the Berg’s angle, and B is the full width at half maximum. The BET surface area of the thin film in air was determined at 700 °C for 5h by a surface analyzer model (Gemini 2375, USA) using N$_2$ as the adsorbate. Fourier transform infrared spectroscopy (FTIR) analysis of the thin film was carried out in a Nicollet Nexus 6700 spectrometer and in the wave number range of 400-4000 cm$^{-1}$ to study the chemical groups. The surface morphology of the thin film was examined by an Auto Probe model CP atomic force microscope (AFM, Park scientific instruments, USA) using a Si$_3$N$_4$ probe.
particles could also be observed in this TEM picture, and most particles were spherical in nature. TEM studies showed powder agglomeration. Generally, it can be said that the increase in specific surface area may improve the catalytic activity. The specific surface area of the final composite powders was determined by the BET surface area analysis, and the calculated surface area was about ~120 m²/g.

Fig. 3 Transmission electron micrographs of the alumina-zirconia particles after calcination at 700 °C for 5h

The X-Ray diffraction pattern has been shown in Fig. 4. It indicated that the calcined coating seemed to be amorphous. This might be due to the organic compounds of the coating. The strong peak at 20=30.2° was assigned to the (111) lattice plan whereas the other weak peak at 20=35.11°, 50.65°, 60.17°, and 63.10° could be ascribed to (200), (220), (131), and (222) lattice planes of tetragonal Zirconia (t-ZrO₂) phase, respectively. The stabilization of t-ZrO₂ could be attributed to the structural similarity of the dopant, Y₂O₃, ZrO₂, and the larger dopant cation radius compared with the Zr⁴⁺ radius [23]. The yttria was changed into yttrium oxide when exposed to the high temperature (700 ºC). Another explanation for the stabilization of the tetragonal phase of zirconia in Y₂O₃ doped ZrO₂ system could be based on the formation of oxygen vacancies resulting from the presence of trivalent cation [24], [25]. Also, the band at 480 cm⁻¹ corresponded to the vibration absorption of Zr–O bond in tetragonal zirconia. This can be explained by the relative contribution of two bonds, Zr–O and Al–O bonds, and it is consistent with the formation of ZrO₂–Al₂O₃. This supports the XRD results and the formation of alumina and zirconia in the present study.

Fig. 4 Phase analysis of the synthesized coating after calcination at 700 °C

AFM images of the thin coating Al₂O₃/ZrO₂ composite on the ceramic plate are shown in Fig. 6. It demonstrated that the surface of the alumina-zirconia coating was compact. The coating was crack-free and consisted of nanoscale crystallites. However, the surface of the coated Al₂O₃/ZrO₂ composite was uneven and used, but the roughness of the catalyst was less than 10 nm.

A. Esterification Reactions

The rate of esterification was strongly influenced by the mass ratio of fatty acid to ethanol. Since the esterification process was reversible, the yield of ethyl esters produced was favored with the excess amount of ethanol. In order to obtain an optimal mass ratio for this process, five experiments were carried out with variable FFA/ethanol mass ratios, between 1:5 and 3:5. Fig. 7 shows the conversion of FFA to ethyl ester as a function of the mass ratio of FFA/ETOH. However, the presented data demonstrated that at a mass ratio of 3:5, the maximum ester yield was obtained. Increasing the mass ratio from 1:1 to 3:5 raised the conversion of ester formation from 25 to 90%. Also, ethyl ester formation was strongly dependent on the reaction temperature.
To evaluate the effect of reaction temperature on the production of ethyl esters, the esterification process was carried out under optimal conditions. Esterification could be conducted at various temperatures. In most cases, the temperature has been kept close to the boiling point of alcohol used in the process [27]. However, high temperatures can reduce the reaction time. In this research, temperature was varied in the range of 150-250 °C. As shown in Fig. 8, the results indicated that increasing the reaction temperature had a favorable influence on the yield of ethyl ester formation.

IV. CONCLUSIONS

In this study, we intended to examine a new heterogeneous base composite catalyst in order to develop an effective catalyst for biodiesel production. A novel sol–gel technique was developed in which the alumina and zirconia sol could be prepared at room temperature from the inorganic salts. This process could be used to prepare uniform mesoporous alumina-zirconia composites. The present work demonstrated the manufacture of a nano-film γ-Al2O3–ZrO2 composite coated on ceramics plates through the sol–gel route. The heterogeneous catalytic reactor had a great ability to produce biodiesel fuel within a short reaction time. It could be concluded that as the mass ratio of FFA/ethanol was increased, the reaction yield and conversion of FFA were increased. The maximum reaction yield at the mass ratio of 3:5 was 90%. At the high temperature (250 °C), high reaction conversion was reached. As expected, at the low temperature, the conversion was low. With the implementation of optimal operational condition, the maximum yield of approximately 90% was achieved. These results showed the possibility for this composite catalyst to act as an effective heterogeneous base catalyst for the manufacture of biodiesel.
