Implication of the Exchange-Correlation on Electromagnetic Wave Propagation in Single-Wall Carbon Nanotubes

A. Abdikian

Abstract—Using the linearized quantum hydrodynamic model (QHD) and by considering the role of quantum parameter (Bohm’s potential) and electron exchange-correlation potential in conjunction with Maxwell’s equations, electromagnetic wave propagation in a single-walled carbon nanotubes was studied. The electronic excitations are described. By solving the mentioned equations with appropriate boundary conditions and by assuming the low-frequency electromagnetic waves, two general expressions of dispersion relations are derived for the transverse magnetic (TM) and transverse electric (TE) modes, respectively. The dispersion relations are analyzed numerically and it was found that the dependency of dispersion curves with the exchange-correlation effects (which have been ignored in previous works) in the low frequency would be limited. Moreover, it has been realized that asymptotic behaviors of the TE and TM modes are similar in single wall carbon nanotubes (SWCNTs). The results show that by adding the function of electron exchange-correlation-potential lead to the phenomena and make to extend the validity range of QHD model. The results can be important in the study of collective phenomena in nanostructures.

Keywords—Transverse magnetic, transverse electric, quantum hydrodynamic model, electron exchange-correlation potential, single-wall carbon nanotubes.

I. INTRODUCTION

As we know, CNTs are rolled up graphene sheets, depending on its radius and the geometric angle can be either metallic or semiconducting. Diameter of SWCNTs varies from 1 to several nanometers [1]-[5]. During the past years, some scientist have used some different theoretical models such as the classical hydrodynamic model [6], [7], semi-classical kinetic theory [8], general quantum-mechanical theory [9] and tight-binding model [10] to describe electronic excitations in SWCNTs. On the other hand, in plasmas with low temperature and high electron density, Pauli’s principle restricts the electrons not to be more than one in each quantum state; such a system is known as quantum or degenerate plasma [11]. In recent years; however, a huge interest has been developed in the area of quantum plasmas which is motivated by its potential application in modern technology, e.g. metallic and semiconductor nanostructures, metal clusters, thin metal films, nanotubes, quantum well and quantum dots, free-electron lasers, etc. [12]-[15]. A common model to investigate the collective dynamics of degenerate electron gas in plasmas and condensed matter systems is QHD model [16]. When density of plasma particles is too high, the thermal de Broglie wavelength associated with each plasma particle may exceed the average inter-particle distance [17]. Since electron exchange-correlation effects are very week; therefore, they are usually ignored in many investigations; however, it has been observed that the electron exchange-correlation effects become significant for high density and low temperature plasmas such as in the ultra-small electronic devices, nanotubes and semiconductor nanostructures (GaAs, GaSb, etc.) [18]-[20]. The electron exchange-correlation potential is a function of electron density and is given by

\[ V_{\text{xc}} = -0.985 \frac{e^2}{\varepsilon} n^{1/3} \left[ 1 + \frac{0.034}{n^{1/3}} a_B \ln \left( 1 + 18.37 n^{1/3} a_B \right) \right], \]

which can be obtained via the adiabatic local-density approximation [12], [21]-[24], where \( a_B = \varepsilon \hbar^2 / m_e e^2 \) is the Bohr radius and \( \varepsilon = 4\pi\varepsilon_0 \) is the effective dielectric permeability of system. The last equation shows that as density increases, the exchange effects increase, while correlation effects decrease [23].

It is necessary to mention that the quantum effects in the plasma dynamics have been performed in a vast number of studies, during the past years. For example, Wei et al. [3] and then Khosravi et al. [25] studied propagation of electromagnetic waves in SWCNTs. In special, surface excitation modes are one of the most interesting aspects in studies of CNTs. Many experimental realizations [26], [27] and theoretical works [28]-[31] have been done to describe the high-frequency excitations (electron oscillations) in these systems. Wei and Wang, using the QHD model, have studied the quantum ion-acoustic waves in SWCNTs [32]. Additionally, several authors have tried to investigate the effects of a static magnetic field on collective modes in CNTs. Fetter has obtained an acoustic branch in addition to the optical [33]. Chiu et al. [34], [35] studied the low-frequency single-particle and collective excitations of SWCNTs in the presence of a magnetic field. Abdikian et al. by exploiting the QHD model and Maxwell’s equations have tried to study the electrostatic waves in CNT which filled by completely electron gas with axial magnetic field [14], [15]. Furthermore, some researchers are interested in TM (Voigt configuration) waves which propagate parallel to the surface of a SWCNT [36], [37].

A. Abdikian is with the Department of Physics, Malayer University, Malayer 65719-95863, Iran (e-mail: abdykian@malayeru.ac.ir).
In the present study, we use the usual linearized QHD model by using the exchange-correlation affects and focus on the propagation of electromagnetic wave in SWCNTs. And then, we wish to distinguish the difference in the TE and TM modes.

II. MATHEMATICAL MODEL

We consider a quantum electron fluid moving on the surface of an infinitely long and infinitesimally thin SWCNT with radius $a$. Let us assume that the density of free-electron fluid is $n_e = 4 \times 38 \text{nm}^{-2}$, corresponding to four valence electrons per carbon atom. For the following calculations, we use cylindrical coordinates $r = (\rho, \phi, z)$. The electromagnetic wave with frequency $\omega$ propagating along the nanotube axis $z$ perturbs the homogeneous electron gas. The velocity of the perturbed density (per unit area) $n_1(r_s, t)$ is considered as $\mathbf{u}(r_s, t)$ where $r_s(\varphi, t)$ are the coordinates of a point at the cylindrical surface of the nanotube. The dynamics of the charged particles are governed by the continuity and the momentum-balance equations [3]

$$\frac{\partial n_1(r_s, t)}{\partial t} + n_1 \nabla_\parallel \cdot \mathbf{u}(r_s, t) = 0,$$  \hspace{1cm} (2)

$$\frac{\partial \mathbf{u}(r_s, t)}{\partial t} = -\frac{e}{m_e} \mathbf{E}(r_s, t) - \frac{\alpha}{n_0} n_1(r_s, t) \nabla_{\parallel} n_1(r_s, t) + \frac{\beta}{n_0} (\nabla_\perp^2 n_1(r_s, t)) + V_{\omega}$$.  \hspace{1cm} (3)

where $n_1$ represents the electron number density, $\mathbf{E} = E_z \hat{e}_z + E_{\phi} \hat{e}_\phi$ is the tangential component of the electromagnetic field and $m_e$ is the effective electron mass. The first term of the right-hand side of (3) is the force, on the electron fluid experiences, due to the tangential component of the electric field, and the roots of the second and the third term come from the internal interaction force in the electron gas and the quantum diffraction effect or electron tunneling (Bohm potential) representing the quantum pressure, respectively. Here, $\alpha = v_F^2 / 2$ is the speed of propagation of the density disturbances in the electron gas and $\beta = (a_B v_F)^2 / 4$ describes single-electron excitations in the electron gas (which $v_F = (2 \pi n a_B^2)^{1/3} v_B$ being the Fermi velocity of the 2D electron gas, $a_B$ and $v_B$ are the Bohr radius and the Bohr velocity, respectively). By expanding the electric field vector $\mathbf{E}(r, t)$ and the magnetic field vector $\mathbf{B}(r, t)$ in the following Fourier forms

$$\mathbf{E}(\mathbf{r}, t) = \sum_{m=-\infty}^{\infty} \int_{-\infty}^{\infty} dq \mathbf{E}(\mathbf{m}, t) e^{i(m\phi + qz - \omega t)}$$,  \hspace{1cm} (4)

One may eliminate the velocity $\mathbf{u}(r_s, t)$ from (1) and (2) and obtain

$$\frac{\partial^2 n_1(r_s, t)}{\partial t^2} = \frac{e n_0}{m_e} \nabla_\parallel \cdot \mathbf{E}(r_s, t) + \alpha \nabla_{\parallel}^2 n_1(r_s, t)$$,  \hspace{1cm} (5)

$$- \beta (\nabla_\perp^2 n_1(r_s, t)) + V_{\omega}$$

where $\omega_c = 0.328 n_{e}^{-1/3} e^2 / m_c [1 + 0.624(1 + 18.37 n_{e}^{-1/3} a_B)]$ [23].

By means of the space-time Fourier transforms for the induced density $n_1(r_s, t)$ on the cylindrical surface,

$$n_1(r_s, q, \omega) = \sum_{m=-\infty}^{\infty} \int_{-\infty}^{\infty} dq N_m(q) e^{i(m\phi + qz - \omega t)}$$,  \hspace{1cm} (6)

where

$$N_m = -i \frac{e n_0}{m_e} \frac{1}{W_m} q_m \cdot \mathbf{E}_m,$$  \hspace{1cm} (7)

where $q_m = q \hat{e}_z + (m / \alpha) \hat{e}_\phi$ and $W_m = \omega_0^2 - \alpha q_m^2 - \beta q_m^4 - \omega_2^2 q_m^2$. By combining the Maxwell’s equations, one may obtain the well-known Helmholtz equations for the $z$-components $E_{zm}$ and $B_{zm}$ of the expanding coefficients $E_{zm}$ and $B_{zm}$

$$\frac{d^2 E_{zm}}{dr^2} + \frac{1}{r} \frac{d E_{zm}}{dr} - \left( \kappa^2 + \frac{m^2}{r^2} \right) E_{zm} = 0$$,  \hspace{1cm} (8)

and

$$\frac{d^2 B_{zm}}{dr^2} + \frac{1}{r} \frac{d B_{zm}}{dr} - \left( \kappa^2 + \frac{m^2}{r^2} \right) B_{zm} = 0$$,  \hspace{1cm} (9)

where $\kappa^2 = q^2 - \omega_0^2 / c^2$ and $c$ is the light speed. In the following two sections, we have tried to derive the plasmon dispersion of low-frequency electromagnetic wave (so $\omega_0 / c \ll q$ [3]) with the TM and TE modes, of course, by solving (8) and (9) by providing appropriate boundary conditions. With the induced density, these boundary conditions can be written as

$$E_{rm}(a)_{r > a} - E_{rm}(a)_{r < a} = \frac{e N_m}{\epsilon_0}$$,  \hspace{1cm} (10)

$$E_{im}(a)_{r > a} - E_{im}(a)_{r < a} = 0$$,  \hspace{1cm} (11)

and

$$B_{rm}(a)_{r > a} - B_{rm}(a)_{r < a} = 0$$,  \hspace{1cm} (12)

As be seen from (10) and (11), by considering the
polarization of the electron fluid on the nanotube surface, the radial component of the electric field \( E_{zm} \) is discontinuous whereas the azimuthal component \( E_{qm} \) of the electric field is continuous at the cylinder \( r = a \).

### III. TM MODE

For the TM mode, the longitudinal magnetic field is zero, i.e., \( B_z = 0 \). From (8), the longitudinal electric field can be expressed by

\[
\begin{align*}
E_{zm}(r) &= C_m I_m(\kappa r) \quad \text{(}r < a\text{)}, \\
E_{zm}(r) &= C_m K_m(\kappa r) \quad \text{(}r > a\text{),}
\end{align*}
\]

where \( I_m(x) \) and \( K_m(x) \) are the modified Bessel functions, and coefficients \( C_m \) and \( D_m \) will be determined by the boundary conditions. With Maxwell’s equations \( \nabla \times \mathbf{E} = -\partial \mathbf{B} / \partial t \) and \( \nabla \times \mathbf{B} = -\epsilon \partial \mathbf{E} / \partial t \), the radial component \( E_{zm} \) and the azimuthal component \( E_{qm} \) of the electric field and the radial component \( B_{zm} \) of the magnetic field can be expressed as

\[
\begin{align*}
E_{rm}(r) &= -i q \frac{dE_{zm}(r)}{dr}, \\
E_{qm}(r) &= \frac{m q}{\kappa^2 r} E_{zm}(r), \quad \text{and}
\end{align*}
\]

and

\[
B_{rm}(r) = \left(1 - \frac{q^2}{\kappa^2}ight) \omega \frac{m}{a r} E_{zm}(r).
\]

Using (7), (14) and (16), the Fourier coefficient \( N_m \) of the induced density is turned into

\[
N_m = -i \frac{en_0}{m_e} \frac{1}{W_m} \left( q E_{zm} + \frac{m}{a} E_{qm} \right),
\]

By substituting (14)-(17) into the boundary conditions, we can obtain the following dispersion relation of the TM mode

\[
\omega^2 = \alpha \left( \kappa^2 + \omega^2 / c^2 + m^2 / a^2 \right) + \beta \left( \kappa^2 + \omega^2 / c^2 + m^2 / a^2 \right) + \gamma \left[ \kappa^2 + \omega^2 / c^2 + m^2 / a^2 \right] \left( I_m(\kappa a) K_m(\kappa a) \right.
\]

where \( \Omega_p = (e^2 n_0 / \epsilon \mu m a) \). For derivation of the above equation, the Wronskian property, \( I_m'(x) K_m(x) - I_m(x) K_m'(x) = 1 / x \), has been used. In order to simplify the notation and with introducing the dimensionless variable \( y = \omega / \Omega_p \) and \( x = \kappa a \), the dispersion relation of the TM mode in the low frequency case can be reduced to the following equation

\[
y^2 = \left( \chi + \lambda_i \right) \left( x^2 + m^2 \right) + \beta_i \left( x^2 + m^2 \right) + \left( x^2 + m^2 \right) \left( I_m(\kappa a) K_m(\kappa a) \right)
\]

where \( \alpha_i = \alpha / (\Omega_p a) \), \( \beta_i = \beta / (\Omega_p a^2) \), \( \lambda_i = v_e^2 / (\Omega_p a) \), and \( \delta = v_e / v_F \).

The behavior of dispersion relation by assuming the two cases of \( x >> |m| \) or \( x << |m| \) will be different and we can distinguish two different dimensionality regimes. For \( x >> |m| \), we may use the well-known asymptotic expressions of the Bessel functions \( I_n(x) \to e^x / \sqrt{2\pi x} \), \( K_n(x) \to \sqrt{\pi / 2x} e^{-x} \) (with the finite \( m \)). Thus, the dispersion relation can be written approximately as

\[
y^2 = \left( \chi + \lambda_i \right) x^2 + \beta_i x^4 + \frac{x}{2}
\]

For large-radius nanotubes, the parameters \( \chi, \beta_i \) and \( \lambda_i \) approached zero and dispersion relation in this case becomes

\[
\omega^2 = \Omega_p^2 \frac{x}{2}
\]

which corresponds to a proper 2D behavior. On the other hand, for \( x << |m| \), we use other well-known expressions of Bessel functions, i.e. \( I_m(x) \to a_m x^m \), \( K_m(x) \to b_m x^{-m} \) (for non-zero \( m \) in where \( a_m = 2^{-m} / \Gamma(m+1) \), \( b_m = 2^{m-1} \Gamma(m+1) \), and \( K_n(x) \to \ln(1.23 / x) \). Then for \( m \neq 0 \), the dispersion relation turns into

\[
\omega^2 = \left( \chi + \lambda_i \right) m^2 + \beta_i m^4 + \frac{m}{2} \Omega_p^2
\]

By comparing (21) and (22), we understand that the former is independent of the dimensions of the tube, while the latter depends strongly on the radius of the tube, and for \( m = 0 \), we have \( \omega = 0 \) implying that no wave could propagate under this condition.

In Fig. 1, the influence of the exchange-correlation potential on the dispersion relation of the TM mode for \( a = 3 a_0 \) with different azimuthal quantum numbers is depicted. As we see, the exchange-correlation effect causes to shift up the curves.
For the TE mode, the longitudinal electric field is zero, i.e., \( E_z = 0 \). From (9), the longitudinal electric field can be expressed by
\[
\begin{align*}
B_{zm}(r) &= C_n I_m(\kappa r) \quad (r < a) \\
B_{zm}(r) &= C_n K_m(\kappa r) \quad (r > a),
\end{align*}
\]
where \( I_m(x) \) and \( K_m(x) \) are the derivatives of the modified Bessel functions with respect to argument \( x = \kappa a \). With the dimensionless variable \( y = \omega / \Omega_b \) and \( x = \kappa a \), the dispersion relation of the TE mode in the low-frequency case can be turned into
\[
y^2 = (\alpha_n^2 + \lambda_n^2)(x^2 + m^2) + \beta_l (x^2 + m^2)^2
+ (x^2 + m^2) I_m'(\kappa a) K_m'(\kappa a),
\]
where \( I_m'(x) \) and \( K_m'(x) \) are the derivatives of the modified Bessel functions with respect to argument \( x = \kappa a \).

Comparing curves with and without the exchange-correlation potential, it can be seen that this effect plays an important role on the dispersion relation for both modes.
same method as a TDR derived by Wei et al. [3]. The asymptotic behaviors of the TE and TM modes were found to be similar in SWCNTs. The dispersion relations were analyzed numerically with typical data of SWCNT. Our calculations have shown the deviation of dispersion curves on the exchange-correlation effects (which were ignored in previous works) in the low frequency limit. The impact of azimuthal quantum number and CNT’s radius on dispersion relation were also discussed. Adding the function of electron exchange-correlation potential \( V_{xc} \) led to the novel phenomena and extended the validity range of QHD model.
