Capacitor Placement in Radial Distribution System for Loss Reduction Using Artificial Bee Colony Algorithm

R. Srinivasa Rao

Abstract—This paper presents a new method which applies an artificial bee colony algorithm (ABC) for capacitor placement in distribution systems with an objective of improving the voltage profile and reduction of power loss. The ABC algorithm is a new population based meta heuristic approach inspired by intelligent foraging behavior of honeybee swarm. The advantage of ABC algorithm is that it does not require external parameters such as cross over rate and mutation rate as in case of genetic algorithm and differential evolution and it is hard to determine these parameters in prior. The other advantage is that the global search ability in the algorithm is implemented by introducing neighborhood source production mechanism which is a similar to mutation process. To demonstrate the validity of the proposed algorithm, computer simulations are carried out on 69-bus system and compared the results with the other approach available in the literature. The proposed method has outperformed the other methods in terms of the quality of solution and computational efficiency.

Keywords—Distribution system, Capacitor Placement, Loss reduction, Artificial Bee Colony Algorithm.

I. INTRODUCTION

The power losses in distribution systems correspond to about 70% of total losses in electric power systems [1]. These losses can be considerably reduced through the installation and control of reactive support equipments, such as capacitor banks, reducing reactive currents in distribution feeders. Furthermore, voltage profiles, power-factor and feeder capability of distribution substations are also significantly improved. The placement of capacitor banks on distribution feeders involves determination of size, type (fixed or switched), location of capacitors at specified load levels. The main objective in capacitor placement problem is to minimize the total cost which is the amount of energy losses of whole system and investment and maintenance cost of installed capacitors while the voltage constraints of each node of the system hold within the limits.

Since, the optimal capacitor placement is a complicated combinatorial optimization problem, many different optimization techniques and algorithms have been proposed in the past. H. Ng et al [2] proposed the capacitor placement problem by using fuzzy approximate reasoning. Sundharajan and Pahwa [3] proposed the genetic algorithm approach to determine the optimal placement of capacitors based on the mechanism of natural selection. Ji-Pyng Chiou et al [4] proposed the variable scale hybrid differential evolution algorithm for the capacitor placement in distribution system. Grainger et al [5]-[6] and Baghzouz and Ertem [7] proposed the concept that the size of capacitor banks was considered as a continuous variable. Bala et al [8] presented a sensitivity-based method to solve the optimal capacitor placement problem.

In this paper, a new algorithm called artificial bee colony (ABC) algorithm is proposed to place the capacitors at candidate locations with an objective of reducing the power losses in the distribution system. The artificial bee colony algorithm is a new meta heuristic approach, proposed by Karaboga [9]-[11]. It is inspired by the intelligent foraging behavior of honey bee swarm. The proposed method is tested on 14 and 33 bus radial distribution systems and results obtained are effective and encouraging.

II. PROBLEM FORMULATION

The objective of capacitor placement in the distribution system is to minimize the annual cost of the system, subjected to certain operating constraints and load pattern. For simplicity, the operation and maintenance cost of the capacitor placed in the distribution system is not taken into consideration. The three-phase system is considered as balanced and loads are assumed as time invariant.

Mathematically, the objective function of the problem is described as:

\[
\text{Minimize } f = \text{Min. } (\text{COST} + \lambda \Delta V_{\min}^2) \tag{1}
\]

where \(\text{COST}\) includes the cost of power loss and the capacitor placement, and will be discussed further later. \(\lambda\) is a penalty function and \(\Delta V_{\min}^2\) is the squared sum of the violated voltage constraint. Moreover, the penalty function satisfies the following properties:

1. if the constraint is not violated, \(\lambda = 0\); 
2. if the constraint is violated, a significant penalty is imposed to cause the objective function to move away from the undesirable solution.

The voltage magnitude at each bus must be maintained within its limits and is expressed as:

\[
V_{\min} \leq |V_k| \leq V_{\max} \tag{2}
\]

where \(|V_k|\) is the voltage magnitude of bus \(k\), \(V_{\min}\) and \(V_{\max}\) are minimum and maximum permissible voltages limits, respectively.
The power loss of any line section connecting buses \( k \) and \( k+1 \) can be computed as

\[
P_{\text{Loss}}(k, k+1) = R_{k,k+1} \frac{(p_k^2 + q_k^2)}{|V_k|^2} \tag{3}
\]

The total power loss in all feeders, \( P_{T,\text{Loss}} \) may then be determined by summing up the losses of all line sections of the feeder, which is given as

\[
P_{T,\text{Loss}} = \sum_{k=0}^{n-1} P_{\text{Loss}}(k, k+1) \tag{4}
\]

Considering the practical capacitors, there exists a finite number of standard sizes which are integer multiples of the smallest size \( Q_0 \). Besides, the cost per kVar varies from one size to another. In general, capacitors of larger size have lower unit prices. The available capacitor size is usually limited to \( \{ Q_0, 2Q_0, 3Q_0, \ldots, LQ_0 \} \) available. Given the annual installation cost for each compensated bus, the total cost due to capacitor placement and power loss change is computed by the formula:

\[
\text{COST} = K_P P_{T,\text{Loss}} + \sum_{k=1}^{n} \left( K_c f + K_c^2 Q_k^2 \right) \tag{5}
\]

where \( n \) is number of candidate locations for capacitor placement, \( K_P \) is the equivalent annual cost per unit of power loss in Rs/(kW-year); \( K_c f \) is the fixed cost for the capacitor placement. The constant \( K_c \) is the annual capacitor installation cost, and, \( k = 1, 2, \ldots, n \) are the indices of the buses selected for compensation. The bus reactive compensation power is limited to

\[
Q_k^C \leq \sum_{k=1}^{n} Q_{Lk} \tag{6}
\]

where \( Q_k^C \) and \( Q_{Lk} \) are the capacitive and inductive reactive powers at bus \( k \) respectively.

III. OVERVIEW OF ARTIFICIAL BEE COLONY ALGORITHM (ABC)

In the ABC algorithm, the colony of artificial bees contains three groups of bees: employed bees, onlookers and scouts. A bee sitting on the dance area for making decision to choose a food source is called an onlooker and a bee going to the food source visited by it previously is named an employed bee. A bee carrying out random search is called a scout. In the ABC algorithm, first half of the colony consists of employed artificial bees and the second half constitutes the onlookers. For every food source, there is only one employed bee. In other words, the number of employed bees is equal to the number of food sources around the hive. The employed bee whose food source is exhausted by the employed and onlooker bees becomes a scout. In the ABC algorithm, each cycle of the search consists of three steps: sending the employed bees onto the food sources and then measuring their nectar amounts; selecting of the food sources by the onlookers after sharing the information of employed bees and determining the nectar amount of the foods; determining the scout bees and then sending them onto possible food sources. At the initialization stage, a set of food source positions are randomly selected by the bees and their nectar amounts are determined. Then, these bees come into the hive and share the nectar information of the sources with the bees waiting on the dance area within the hive. At the second stage, after sharing the information, every employed bee goes to the food source area visited by her at the previous cycle since that food source exists in her memory, and then chooses a new food source by means of visual information in the neighborhood of the present one. At the third stage, an onlooker prefers a food source area depending on the nectar information distributed by the employed bees on the dance area. As the nectar amount of a food source increases, the probability with which that food source is chosen by an onlooker increases, too. Hence, the dance of employed bees carrying higher nectar recruits the onlookers for the food source areas with higher nectar amount. After arriving at the selected area, she chooses a new food source in the neighborhood of the one in the memory depending on visual information. Visual information is based on the comparison of food source positions. When the nectar of a food source is abandoned by the bees, a new food source is randomly determined by a scout bee and replaced with the abandoned one. In our model, at each cycle at most one scout goes outside for searching a new food source and the number of employed and onlooker bees were equal.

The probability \( P_i \) of selecting a food source \( i \) is determined using the following expression:

\[
P_i = \frac{f_{it_i}}{\sum_{n=1}^{S_N} f_{it_n}} \tag{7}
\]

where \( f_{it_i} \) is the fitness of the solution represented by the food source \( i \) and \( S_N \) is the total number of food sources. Clearly, with this scheme good food sources will get more onlookers than the bad ones. After all onlookers have selected their food sources, each of them determines a food source in the neighborhood of his chosen food source and computes its fitness. The best food source among all the neighboring food sources determined by the onlookers associated with a particular food source \( i \) and food source \( i \) itself, will be the new location of the food source \( i \). If a solution represented by a particular food source does not improve for a predetermined number of iterations then that food source is abandoned by its associated employed bee and it becomes a scout, i.e., it will search for a new food source randomly. This tantamount to assigning a randomly generated food source (solution) to this scout and changing its status again from scout to employed. After the new location of each food source is determined, another iteration of ABC algorithm begins. The whole process is repeated again and again till the termination condition is satisfied.

The food source in the neighborhood of a particular food source is determined by altering the value of one randomly chosen solution parameter and keeping other parameters unchanged. This is done by adding to the current value of the
chosen parameter the product of a uniform variate in [-1, 1]
and the difference in values of this parameter for this food
source and some other randomly chosen food source.

Formally, suppose each solution consists of \( d \) parameters
and let \( x_i = (x_{i1}, x_{i2}, \ldots, x_{id}) \) be a solution with parameter
values \( x_{i1}, x_{i2}, \ldots, x_{id} \). In order to determine a solution
\( v_i \) in the neighborhood of \( x_i \), a solution parameter \( j \) and
another solution \( x_k = (x_{k1}, x_{k2}, \ldots, x_{kd}) \) are selected
randomly. Except for the value of the selected parameter \( j \), all other parameter values of \( v_i \) are same as \( x_i \), i.e.,
\[
\forall j \neq i, v_i (x_{ij} = x_{ij})
\]
\[
v_i (x_{ij}) = x_{ij} + u(x_{ij} - x_{kj})
\]
where \( u \) is a uniform variate in [-1, 1]. If the resulting value
falls outside the acceptable range for parameter \( j \), it is set to
the corresponding extreme value in that range.

The proposed artificial bee colony algorithm is summarized
as follows:
1. Read input data and Initialize MNC;
2. Initialize the population, \( x_1 = (Q_{11}, Q_{12}, \ldots, Q_{ij}) \);
3. Evaluate fitness value for each employed bee by
   using the following formula
   \[
   \text{fitness} = \frac{1}{1 + \text{Power loss}}
   \]
4. Initialize cycle=1;
5. Generate new population (solution) \( v_i \) in the neigh-
   borhood of \( x_i \) for employed bees using equation 9
   and evaluate them;
6. Apply the greedy selection process between \( x_i \) and
   \( v_i \);
7. Calculate the probability values \( P_i \) for the solutions
   \( x_i \) by means of their fitness values using the equation
   8;
8. Produce the new populations \( v_i \) for the onlookers
   from the populations \( x_i \), selected based on \( P_i \) by
   applying roulette wheel selection process, and evaluate
   them;
9. Apply the greedy selection process for the onlookers
   between \( x_i \) and \( v_i \);
10. Determine the abandoned solution, if exists, and
    replace it with a new randomly produced solution
    \( x_i \) for the scout bees using the following equation:
    \[
    x_{ij} = \min_j + \text{rand}(0, 1) \times (\max_j - \min_j);
    \]
11. Memorize the best solution achieved so far;
12. cycle=cyce+1;
13. if cycle<\( MIC \), go to step 5, otherwise go to step 14;

IV. TEST RESULTS

The proposed method was tested on 69-bus radial distribution
system and results have been obtained to evaluate its
effectiveness. The algorithm of this method was programmed
in MATLAB environment and run on a Pentium IV, 3-GHz
personal computer with 0.99 GB RAM.

69 - bus system: To test the proposed method, a 69-node
radial distribution system shown in Fig. 1 has been taken as
an example network [12]. Line data and nominal load data for
this system are given in Appendix A.

For this test feeder, \( K_P \) is selected is selected to be 168
$/\text{kW-year} \ [7]$. Only fixed capacitors are used in the analysis
and the marginal cost of capacitors given [14] are used to
compute the total annual cost. The fixed cost of the capacitor,
\( Kc_f \) is selected as $1000 [15]$ with a life expectancy of ten
years (the maintenance and running costs are neglected). The
substation voltage (bus 1) is considered as 1.0 p.u. The limit
of voltage magnitude is taken between 0.90 to 1.10 p.u.

Using sensitivity analysis the buses are ordered according to
their sensitivity value (\( \frac{\partial P_{\text{Linloss}}}{\partial Q_{\text{eff}}} \)) (i.e. nodes 61, 64,
59, 65, . . .). Top three nodes are selected as candidate locations
(i.e. nodes 61, 64 and 59) to reduce the search space and then
the amount to be injected in the selected nodes is optimized
by ABC. Using this method, the capacitors of rating 700, 800,
100 kVAR are placed at the optimal candidate locations 61,
64, and 59, respectively. The simulation results are shown
in I. Table I also shows the comparison of results Particle
Swarm Optimization (PSO) [13]. The minimum voltage before
capacitor installation is 0.90919 p.u (bus 65) and is raised to
0.93693 p.u (bus 65) after capacitor installation.

From Table I, it is observed that the power loss obtained
with the proposed method is approximately 10 kW less than
that of (PSO) [13]. The optimal candidate locations are the same with all methods but the total kVAr injected by the proposed method is less by 200 kVAr than that of PSO method. The net saving in the cost by the proposed method is 5% less than that of the PSO method.

V. CONCLUSION

In the present work, a new population based artificial bee colony algorithm (ABC) has been proposed to solve capacitor placement problem in distribution system. Simulations are carried on 69-bus systems and results are compared with the other population based method PSO. The results obtained by the proposed method out perform the other methods in terms of quality of the solution and computation efficiency.

The main advantage of ABC algorithm is that it does not require external parameters such as cross over rate and mutation rate etc, as in case of genetic algorithms, differential evolution and other evolutionary algorithms and these are hard to determine in prior. The other advantage is that the global search ability in the algorithm is implemented by introducing neighborhood source production mechanism which is a similar to mutation process.
