Refined Buckling Analysis of Rectangular Plates Under Uniaxial and Biaxial Compression

V. Piscopo

Abstract—In the traditional buckling analysis of rectangular plates the classical thin plate theory is generally applied, so neglecting the plating shear deformation. It seems quite clear that this method is not totally appropriate for the analysis of thick plates, so that in the following the two variable refined plate theory proposed by Shimpi (2006), that permits to take into account the transverse shear effects, is applied for the buckling analysis of simply supported isotropic rectangular plates, compressed in one and two orthogonal directions.

The relevant results are compared with the classical ones and, for rectangular plates under uniaxial compression, a new direct expression, similar to the classical Bryan’s formula, is proposed for the Euler buckling stress. As the buckling analysis is a widely diffused topic for a variety of structures, such as ship ones, some applications for plates uniformly compressed in one and two orthogonal directions are presented and the relevant theoretical results are compared with those ones obtained by a FEM analysis, carried out by ANSYS, to show the feasibility of the presented method.

Keywords—Buckling analysis, Thick plates, Biaxial stresses

I. INTRODUCTION

The buckling problem of rectangular plates, under the action of uniaxial and biaxial stresses, is generally solved applying the classical thin plate theory, in which the transverse shear deformation is neglected. Obviously, when the thickness is not negligible, as regards the plate dimensions, the classical theory becomes not totally appropriate and a new formulation, that permits to take into account the shear effects, is required. In the past, to overcome this lack, different shear deformable theories were presented by several authors, such as Reissner [7], Mindlin [8], Levinson [9], Reddy [10], Shimpi [2].

In the following the Shimpi theory, based on two variable coupled governing equations for the bending and shear displacement fields, is applied for the buckling analysis of simply supported rectangular plates under the action of uniaxial and biaxial stresses. The theory accounts for the cubic variation of the in-plane displacements through the plate thickness and the transverse shear strains, which vanish on the top and bottom faces of the plate. The main advantage of the theory is that the governing equations have been derived using the Hamilton’s principle, so that they are certainly consistent with the assumed displacement field.

The obtained results are compared with the classical project formulas for buckling analysis and particularly with the Bryan expression for simply supported rectangular plates under uniaxial compression. This last formula is easily obtained by developing into appropriate double sine trigonometric series the deflection surface of the buckled plate. So, denoting by \( m \) the number of half-waves in the direction of compression, by \( t \) the plating thickness, \( E \) and \( \nu \) the Young and Poisson modulus, \( a \) and \( b \) the longer and shorter sides of the panel and by \( \alpha = a/b \) the plating aspect ratio, the Bryan’s formula for the Euler buckling stress can be so expressed:

\[
\sigma_x = \frac{\pi^2 E}{12(1-\nu^2)} \left( \frac{t}{b} \right)^2 \left( \frac{a}{m} \right)^2
\]  

The magnitude of the Euler load depends on the panel aspect ratio \( \alpha \) and also on \( m \), which gives the number of half-waves into which the plate buckles. The eq. (1) is generally developed as follows:

\[
\sigma_x = \frac{\pi^2 E}{12(1-\nu^2)} \left( \frac{t}{b} \right)^2 K_i
\]  

having denoted by \( K_i \) the buckling factor, defined as:

\[
K_i = \begin{cases} 
4.00 & \text{if } \alpha > 1 \\
\left( \frac{\alpha + 1}{\alpha} \right)^2 & \text{if } \alpha \leq 1 
\end{cases}
\]  

The classical approach for rectangular plates under biaxial compression is quite similar and some project curves are generally used to evaluate the Euler stresses at which buckling occurs.

In the following the buckling analysis of thick rectangular plates is carried out applying the Shimpi theory and so taking into account the shear deformations. A method, different from the classical energy one and substantially based on the nontrivial solution of the two variable coupled governing equations for the bending and shear displacement fields, is adopted to evaluate the critical buckling load. A new project formula, that differs from the Bryan’s one for a corrective factor function of the ratio \( t/b \), is also proposed for plates under uniaxial compression.

Finally, some applications are presented for platings uniformly compressed along one and two orthogonal directions, varying the thickness and the plating aspect ratio. The theoretical Euler buckling stresses, corrected taking into
account the shear effects, are also compared with those ones obtained by a FEM analysis carried out by ANSYS.

II. THEORETICAL DEVELOPMENT

Let us refer to the coordinate system of Fig.1 with z axis having the origin on the plate middle plane. The basic assumptions of the two variable refined Shimpi theory are:

1. the displacements are small, if compared with the plating thickness;
2. the stress $\sigma_{x}$ is negligible respect to the in-plane stresses $\sigma_{x}$;
3. the displacement $w(x, y)$ normal to the plate middle plane is the sum of two components of bending and shear $w_{b}(x, y)$ and $w_{s}(x, y)$ respectively;
4. the in-plane displacements $u(x, y)$ and $v(x, y)$ along the $x$ and $y$ axes include two components of bending and shear and one component $u_{s}(x, y)$ and $v_{s}(x, y)$ due to the in-plane normal forces;
5. the bending components $u_{s}(x, y)$ and $v_{s}(x, y)$ are similar to those ones of the classical thin plate theory: $u_{s}(x, y) = -z \frac{\partial w_{s}}{\partial x}$ and $v_{s}(x, y) = -z \frac{\partial w_{s}}{\partial y}$;
6. the shear components $u_{s}(x, y)$ and $v_{s}(x, y)$ are related to the vertical shear displacement field $w_{s}$.

The Hamilton’s principle is used to derive the equations of motion appropriate to the assumed displacement field (4), so imposing the following condition:

$$\int \left( \partial U + \partial V - \partial T \right) dt = 0$$

having denoted by $U$ the strain energy, $V$ the work done by the applied forces and $T$ the kinetic energy. Denoting by

$$D = \frac{E t^{2}}{12(1-\nu^{2})}$$

the plate flexural rigidity and by $G$ the Coulomb modulus, the governing equations can be finally expressed as follows, [2]:

$$\begin{aligned}
D \frac{\partial^{4} w_{s}}{\partial x^{4}} &= N_{x} \left( \frac{\partial^{2} w_{s}}{\partial x^{2}} + \gamma \frac{\partial^{2} w_{s}}{\partial y^{2}} \right) \\
D \frac{\partial^{4} w_{s}}{\partial x^{2} \partial y^{2}} &= N_{y} \left( \frac{\partial^{2} w_{s}}{\partial x^{2}} + \gamma \frac{\partial^{2} w_{s}}{\partial y^{2}} \right)
\end{aligned}$$

where $N_{x}$ and $N_{y}$ are the in-plane forces per unit of length, directed along the $x$ and $y$ axes respectively and $N_{w}$ is the shear in-plane force per unit of length. Assuming that these forces are constant throughout the plate, $N_{w} = 0$ and $N_{y} = y N_{x}$, with $0 \leq y \leq 1$, the eq. (6) can be rewritten as follows:

$$\begin{aligned}
D \frac{\partial^{4} w_{s}}{\partial x^{4}} &= N_{x} \left( \frac{\partial^{2} w_{s}}{\partial x^{2}} + \gamma \frac{\partial^{2} w_{s}}{\partial y^{2}} \right) \\
D \frac{\partial^{4} w_{s}}{\partial x^{2} \partial y^{2}} &= N_{y} \left( \frac{\partial^{2} w_{s}}{\partial x^{2}} + \gamma \frac{\partial^{2} w_{s}}{\partial y^{2}} \right)
\end{aligned}$$

As the plate is considered as simply supported along all edges, the boundary conditions are satisfied by taking for the deflection surface of the buckled plate the following double sine trigonometric series for the bending and shear components:

$$\begin{aligned}
w_{s}(x, y) &= \sum_{m=0}^{\infty} \sum_{n=1}^{\infty} w_{m}^{s} \sin \frac{m \pi x}{a} \sin \frac{n \pi y}{b} \\
w_{s}(x, y) &= \sum_{m=0}^{\infty} \sum_{n=1}^{\infty} w_{m}^{s} \sin \frac{m \pi x}{a} \sin \frac{n \pi y}{b}
\end{aligned}$$

Substituting eq. (8) into (7), the unknown amplitudes $w_{m}^{s}$ and $w_{m}^{s}$ are solution of the following homogeneous equation system:

$$\begin{aligned}
A_{m} w_{m}^{s} + A_{m} w_{m}^{s} &= 0 \\
A_{m} w_{m}^{s} + A_{m} w_{m}^{s} &= 0
\end{aligned}$$

with:

Fig. 1 Plate reference system

Starting from these basic assumptions, the displacement field becomes:

$$\begin{aligned}
u(x, y) &= u_{s}(x, y) - z \frac{\partial w_{s}}{\partial x} + \frac{1}{4} z \frac{5}{3 \pi} \frac{\partial w_{s}}{\partial x} \\
v(x, y) &= v_{s}(x, y) - z \frac{\partial w_{s}}{\partial y} + \frac{1}{4} z \frac{5}{3 \pi} \frac{\partial w_{s}}{\partial y} \\
w(x, y) &= w_{s}(x, y) + w_{s}(x, y)
\end{aligned}$$

(4)
The equation for calculating the Euler stress value $\sigma$ can be now derived by equating to zero the determinant of the above system of equations, so obtaining:

$$
\sigma = \frac{\pi^2 E}{12(1-\nu^2)} \left( \frac{t}{b} \right)^2 \frac{\left( \frac{m^2}{\alpha^2} + \gamma^2 \right)}{\frac{m^2}{\alpha^2} + \nu^2} F\left(\frac{t}{b},m,n,v,\alpha\right)
$$

with:

$$
F\left(\frac{t}{b},m,n,v,\alpha\right) = \frac{1 + \left( \frac{t}{b} \right)^2 \frac{\pi^2}{420(1-\nu)} \left( \frac{m^2}{\alpha^2} + \nu^2 \right)}{1 + 85\left( \frac{t}{b} \right)^2 \frac{\pi^2}{420(1-\nu)} \left( \frac{m^2}{\alpha^2} + \nu^2 \right)}
$$

For plates under uniaxial compression the Euler buckling stress can be immediately derived considering that the plate buckles in such a way that there can be several half-waves in the direction of compression, but only one half-wave in the perpendicular direction. Thus, a new expression for the Euler stress, that differs from the Bryan’s formula for the shear correction factor $F(t/b,m,n,v,\alpha)$, is obtained:

$$
\sigma = \frac{\pi^2 E}{12(1-\nu^2)} \left( \frac{t}{b} \right)^2 \left( \frac{\alpha}{m} + \frac{\nu}{\alpha} \right)^2 F\left(\frac{t}{b},m,n,v,\alpha\right)
$$

with:

$$
F\left(\frac{t}{b},m,n,v,\alpha\right) = \frac{1 + \left( \frac{t}{b} \right)^2 \frac{\pi^2}{420(1-\nu)} \left( \frac{m^2}{\alpha^2} + 1 \right)}{1 + 85\left( \frac{t}{b} \right)^2 \frac{\pi^2}{420(1-\nu)} \left( \frac{m^2}{\alpha^2} + 1 \right)}
$$

Fig. 2 Buckling factor $k_1$ for thick-plates under uniaxial compression ($\nu = 0.30; \gamma = 0.0$)
For plates under biaxial compression with $0 < \gamma < 0.5$ it is possible to verify that the plate always buckles in such a way that $n=1$, while the number of half-waves in $x$-direction varies; instead when $0.5 \leq \gamma \leq 1.0$ the plate buckles in such a way that there is only one half-wave in both directions. In figg. 3 and 4, for $\gamma = 0.1$ and $\gamma = 0.4$, the buckling factors are shown for different values of the plating aspect ratio. In figg. 5 and 6 the same factors are shown for $\gamma = 0.7$ and $\gamma = 1.0$ (in this case, for scale reasons, the only curves with $\nu/b=0.075$ are presented). It is noticed that the thick curves always refer to the classical values for thin plates and the Poisson modulus has been always assumed equal to 0.30.

III. NUMERICAL APPLICATIONS

To show the feasibility of the presented formulas, several buckling analyses for steel platings of ship structures, subjected to uniaxial and biaxial compression, are shown. A comparison with the relevant results obtained by a FEM analysis, carried out by ANSYS, is also presented to validate the proposed formulas. In ANSYS some eigenvalue buckling analyses have been performed and the convergence of the solution has been studied by thickening the mesh (the last one with a mean element length of 0.005 m). The chosen element is the 4-node finite strain SHELL181, suitable for analyzing thin to moderately thick structures and well-suited for linear, large rotation, and/or large strain nonlinear applications. The analyzed panels are:

1. Case 1: a=0.25 m; b=1.00 m; t=10-20-30 mm;
2. Case 2: a=1.00 m; b=1.00 m; t=10-20-30 mm;
3. Case 3: a=4.00 m; b=1.00 m; t=10-20-30 mm.

It was assumed that they are in high strength steel with $E = 2.06 \times 10^{11}$ Pa, $\nu = 0.3$, $e_{HR} = 355$ N/mm$^2$.

A. Plates under uniaxial compression

In tables I.A, II.A and III.A the Euler forces per unit of length $A_b$ are shown for different values of the ratio $t/b$. The convergence of the solution obtained by ANSYS is also studied: in all cases it is quite quickly achieved and a very good accordance with the proposed buckling formulas is found. In tables I.B, II.B and III.B the relevant critical buckling stresses are shown.

From the obtained results, it seems quite clear that the refined buckling analysis always furnishes, respect to the classical thin plate theory, results closer to those ones obtained by the FEM analysis and the relevant percentage differences of theoretical results grow up, when the ratio $t/b$ increases, as it would be predictable.

Anyway, it is fundamental to note that these differences are certainly lower if referred to the critical stress value, the most important parameter in a buckling analysis. It implies that the introduction of the shear correction factor always permits to obtain results closer to the FEM values, even if not particularly different by those ones obtained by some eigenvalue buckling analyses carried out for steel platings of ship structures. The theoretical buckling loads have been compared with the relevant values obtained by the FEM analysis. The convergence of the solution obtained by ANSYS has been studied and in all cases it was quite quickly achieved. From the analysis it is clear that there is a very good accordance with the proposed formulas and the FEM values and also in this case the thick plate theory furnishes values of the Euler buckling loads lower than the classical ones.

B. Plates under biaxial compression

In tables IV, V and VI the Euler forces per unit of length are shown for platings under biaxial compression with $\gamma = 1.0$, for different values of the ratio $t/b$.

The convergence of the solution obtained by ANSYS has been studied and in all cases it was quite quickly achieved. From the analysis it is clear that there is a very good accordance with the proposed formulas and the FEM values and also in this case the thick plate theory furnishes values of the Euler buckling loads lower than the classical ones.

IV. CONCLUSIONS

In this paper the refined plate theory proposed by Shimpi (2006) has been applied for the buckling analysis of platings, simply supported along all edges and compressed in one and two orthogonal directions. For plates under uniaxial compression a new direct formula, similar to the Bryan’s one, has been derived: this expression permits to take into account the shear effects by means of a shear correction factor, as function of the half waves’ number in the loaded direction, the panel aspect ratio, the Poisson modulus and the thickness ratio $t/b$. Some curves, that permit to easily evaluate the buckling coefficient for plates under uniaxial and biaxial compression (assuming in this case $\gamma = 1.0$), are also presented.

Finally, some numerical applications have been carried out for steel platings of ship structures. The theoretical buckling loads have been compared with the relevant values obtained by some eigenvalue buckling analyses carried out by ANSYS. It was found that the refined theory always furnishes, respect to the classical one, results closer to the values obtained by the FEM analysis. The convergence of the solution obtained by ANSYS has also been studied by thickening the mesh.

As this method permits to obtain simple closed project formulas, it can be satisfactory applied to the buckling analysis of plates. Obviously, this refined buckling analysis can also be extended to platings under the combined action of uniaxial and edge shear forces, even if in this case the proposed solution method is not available and the classical energy method must be applied.
