Computationally Efficient Adaptive Rate Sampling and Adaptive Resolution Analysis

Saeed Mian Qaisar, Laurent Fesquet, and Marc Renaudin

Abstract—Mostly the real life signals are time varying in nature. For proper characterization of such signals, time-frequency representation is required. The STFT (short-time Fourier transform) is a classical tool used for this purpose. The limitation of the STFT is its fixed time-frequency resolution. Thus, an enhanced version of the STFT, which is based on the cross-level sampling, is devised. It can adapt the sampling frequency and the window function length by following the input signal local variations. Therefore, it provides an adaptive resolution time-frequency representation of the input. The computational complexity of the proposed STFT is deduced and compared to the classical one. The results show a significant gain of the computational efficiency and hence of the processing power. The processing error of the proposed technique is also discussed.

Keywords—Level Crossing Sampling, Activity Selection, Adaptive Resolution Analysis, Computational Complexity.

I. CONTEXT OF THE STUDY

This work is a contribution in the development of smart mobile systems. The goal is to reduce their cost, size, processing noise, electromagnetic emission and especially power consumption, as they are remotely powered by batteries. This can be done by smartly reorganizing their associated signal processing theory and architecture. The idea is to combine the signal event driven processing with the clock less circuit design in order to reduce the system activity.

Almost all natural signals like speech, seismic and biological signals are of non stationary nature. Moreover the man made signals like Doppler, ASK (Amplitude Shift Keying), FSK (Frequency Shift Keying) etc. also lie in the same category. The spectral contents of these signals vary with time, which is a direct consequence of the signal generation process [5].

Classical systems are based on the Nyquist signal processing architectures. They cannot sense the input signal local variations and therefore they process it at a fixed pace. Thus, in case of low activity sporadic signals like electrocardiogram, phonocardiogram, seismic signals etc. they produce a large number of useless samples without any relevant information. It causes a useless increase in the system activity and so a useless increase of the power consumption.

II. LCSS (LEVEL CROSSING SAMPLING SCHEME)

In the case of LCSS, a sample is captured only when the input analog signal \( x(t) \) crosses one of the predefined threshold levels [1]. The samples are not uniformly spaced in time because they depend on \( x(t) \) variations as it is clear from Fig. 1. Thus, the non-uniformity in the sampling process reflects the signal local characteristics [12].

According to [1], the sampling instants of a non-uniformly sampled signal obtained with the LCSS are defined by Equation 1.

\[
\begin{align*}
      t_n &= t_{n-1} + d_{t_n} \cdot \\
      d_{t_n} &= \tau_n - t_{n-1}.
\end{align*}
\]

Where \( t_n \) is the current sampling instant, \( t_{n-1} \) is the previous one and \( d_{t_n} \) is the time delay between the current and the previous sampling instants (cf. Equation 2).

III. PROPOSED ADAPTIVE RESOLUTION STFT

The block diagram of the proposed STFT is shown in Fig. 2. The description of different blocks is given in the following subsections.
A. AADC (Asynchronous Analog to Digital Converter)

The AADC [2], is employed for digitizing \( x(t) \). An \( M \)-bit resolution AADC has \( 2^M - 1 \) quantization levels which are disposed according to \( x(t) \) amplitude dynamics. In the studied case, the levels are uniformly spaced.

Let \( \delta \) be the AADC processing delay for one sample. Thus for proper signal capturing the \( x(t) \) must satisfy the tracking condition [2], given by Expression 3, where \( q \) is the AADC quantum, which is defined by Equation 4. In Equation 4, \( N_{pq} \) and \( M \) represent the amplitude dynamics and the resolution of the AADC respectively.

\[
\frac{dx(t)}{dt} \leq \frac{q}{\delta} \quad (3) \quad q = \frac{\Delta V_p}{2^M - 1} \quad (4) \quad \frac{dx(t)}{dt} \leq 2\pi\Delta x(t) f_{\text{max}} \quad (5)
\]

The left hand side of Expression 3 is the slope of \( x(t) \). The upper bound on the slope of a band limited signal is defined by the Bernstein’s inequality [2], given by Expression 5. In Expression 5, \( f_{\text{max}} \) and \( \Delta x(t) \) represent the bandwidth and the amplitude dynamics of the \( x(t) \) respectively. Thus, In order to respect the tracking condition, a band pass filter with pass-band \( [f_{\text{max}}, f_{\text{max}}] \) is employed at the AADC input.

In order to avoid the complete AADC resolution, in the studied case, \( \Delta x(t) \) is always adapted to match \( M_{pq} \). For an \( M \)-bit resolution AADC, the maximum and the minimum sampling frequencies [11, 13] are defined by Equations 6 and 7 respectively.

\[
F_{s_{\text{max}}} = 2f_{\text{max}}(2^M - 1). \quad (6) \quad F_{s_{\text{min}}} = 2f_{\text{min}}(2^M - 1). \quad (7)
\]

Where, \( f_{\text{max}} \) is the fundamental (lowest) frequency of \( x(t) \). \( F_{s_{\text{max}}} \) and \( F_{s_{\text{min}}} \) are the maximum and minimum sampling frequencies of the AADC.

B. EASA (Enhanced Activity Selection Algorithm) and Window Selector

The EASA is an improved version of the ASA [8]. The relevant (active) parts of the non-uniformly sampled signal obtained with the AADC are selected by the EASA. This selection process corresponds to the adaptive length rectangular windowing process.

The main difference between the ASA and the EASA is the choice of the upper bound on the selected window length. For the ASA the time length in seconds and for the EASA the number of samples is chosen as the upper bound. The EASA is defined as follow:

\begin{verbatim}
While (dt, ≤ T_C/2 and N^i ≤ N_{ref})
end
\end{verbatim}

Where, \( T_0 = 1/f_{\text{min}} \) is the fundamental period of \( x(t) \). \( T_0 \) and \( dt, \) detect parts of the non-uniformly sampled signal with activity. The condition on \( dt, \) chosen in order to satisfy the Nyquist sampling criterion for \( f_{\text{max}} \) when sampling \( x(t) \) non-uniformly with the AADC. \( N \) represents the number of non-uniform samples lie in the \( j^{th} \) selected window, which lie on the \( j^{th} \) active part of the non-uniformly sampled signal.

Where, \( i \) and \( j \) both belong to the set of natural numbers \( \mathbb{N} \). \( N_{\text{ref}} \) represents the upper bound on \( N \). The choice of \( N_{\text{ref}} \) depends on the \( x(t) \) characteristics and the system parameters. The above described loop repeats for each selected window, which occurs during the observation length of \( x(t) \). Every time before starting the next loop, \( i \) is incremented and \( N \) is initialized to zero.

The EASA displays interesting features with the LCSS, which are not available in the classical case. It selects only the active parts of the non-uniformly sampled signal, obtained at the AADC output. Moreover, it correlates the length of the selected window with the input signal local characteristics.

The window selector implements the condition given by Expression 8. The output of window selector is the window decision \( \mathcal{D}_i \), which drives the switch state for the \( i^{th} \) selected window (cf. Fig. 2). Jointly, the EASA and the window selector, provide an efficient spectral leakage reduction in the case of transient signals. Indeed, spectral leakage occurs due to the signal truncation problem, which causes to process the non integer number of cycles in the observation interval. Usually an appropriate smoothening (cosine) window function is employed to reduce the signal truncation, in the classical case. For the proposed case, as long as the condition 8 is true, the leakage problem is resolved by avoiding the signal truncation [8]. As no signal truncation occurs so no cosine window is required. In this case, \( \mathcal{D} \) is set to 0, which drives the switch to state 0 in Fig. 2. Otherwise an appropriate cosine window is employed to reduce the signal truncation problem. In this case, \( \mathcal{D} \) is set to 1, which drives the switch to state 1 in Fig. 2.

\[
\text{if } (N^i \leq N_{\text{ref}} \text{ and } (Td^i = t_i - t_i^{\text{in}}) > \frac{T_0}{2}) \quad (8)
\]

In expression 8, \( t_i^j \) represents the \( l^j \) sampling instant of the \( i^{th} \) selected window and \( t_i^{\text{in}} \) represents the last sampling instant of the \( (i-1)^{th} \) selected window.

For proper spectral representation, the condition given by Expression 9 should be satisfied [8]. Where, \( L_i \) is the length in seconds of the \( i^{th} \) selected window. In order to satisfy this condition for the worst case, which occurs for \( F_{s_{\text{max}}} \) \( N_{\text{ref}} \) is calculated for an appropriate reference window length \( L_{\text{ref}} \). \( L_{\text{ref}} \) has to satisfy the condition: \( L_{\text{ref}} \geq T_0 \). The process of calculating \( N_{\text{ref}} \) is given by Equation 10.

\[
L_i \geq T_0 \quad \text{and} \quad N_{\text{ref}} = L_{\text{ref}} \cdot F_{s_{\text{max}}} \quad \text{.} \quad (9)
\]

The lower and the upper bounds on \( L_{\text{ref}} \) are posed respectively by \( T_0 \) and the system resources (the maximum sample frame which system can process at once). For \( N_{\text{ref}} \) (cf. Equation 10), the condition 9 holds for all selected windows except for the case when the actual length of the \( j^{th} \) activity is less than \( T_0 \).
C. Adaptive Rate Sampling

The AADC sampling frequency is correlated to \( x(t) \) local variations [8, 11]. Let \( F_s' \) represents the AADC sampling frequency for the \( i \)th selected window. \( F_s' \) can be specific for each selected window, depending upon \( L' \) and the slope of \( x(t) \) part lying within this window [8]. \( F_s' \) can be calculated by using the following equations.

\[
L' = t_{\text{max}} - t_{\text{min}}. \quad (11) \quad F_s' = \frac{N}{L'}. \quad (12)
\]

In Equation 11, \( t_{\text{max}} \) and \( t_{\text{min}} \) are the final and the initial times of the \( i \)th selected window. The upper and the lower bounds on \( F_s' \) are posed by \( F_{s_{\text{max}}} \) and \( F_{s_{\text{min}}} \) respectively.

The selected data obtained with the EASA can be used directly for further non-uniform digital processing [3, 12]. However in the studied case, the selected data is resampled uniformly. It enables to take advantage of both non-uniform and uniform signal processing tools [8, 11, 13]. Due to this resampling, there will be an additional error. Nevertheless, prior to this transformation, one can take advantage of the inherent over-sampling of the relevant signal parts in the system [11, 13]. Hence, it adds to the accuracy of the post resampling process [4]. The NNRI (nearest neighbour resampling interpolation) is employed for data resampling. It is a simple interpolation method as it employs only one non-uniform observation for each resampled observation. Thus, it is efficient in terms of the computational complexity. Moreover, it provides an unbiased estimate of the variance of the original signal, due to this reason it is also known as a robust interpolation method [9, 10]. The detailed reasons of inclination towards NNRI are discussed in [8, 9, 10].

The interpolation process changes the properties of the resampled signal compared to the original one. The properties of the resampled signal depend upon the interpolation technique used to resample it [9, 10]. A study on the interpolation error is made by taking into account an academic signal, known formally. If \( (r_n, x_n) \) represent the time-amplitude pairs of the \( n \)th interpolated sample. Then the original sample amplitude \( x_0 \) can be mathematically calculated for \( r_n \), as the input signal is analytically known. Now the interpolation error per interpolated point \( IE_n \) is given by the absolute difference between \( x_0 \) and \( x_n \). The process is given by Equation 13. The mean interpolation error for the \( i \)th selected window \( \text{MIE} \) is given by Equation 14.

\[
IE_n = |x_0 - x_n|. \quad (13) \quad \text{MIE} = \frac{1}{N_r'} \sum_{n=1}^{N_r'} IE_n. \quad (14)
\]

In Equation 14, \( N_r' \) is the number of resampled data points lie in the \( i \)th selected window. A reference sampling frequency \( F_{\text{ref}} \) is chosen such as it remains greater than and closest to the \( F_{\text{Nyq}} = 2f_{\text{max}} \). Depending upon the values of \( F_{\text{ref}} \) and \( F_s' \) the resampling frequency for the \( i \)th selected window \( F_{s_i} \), can be adapted (cf. Fig. 2).

For the case, \( F_{s_i} > F_{\text{ref}}, F_{s_i} \) is chosen as: \( F_{s_i} = F_{\text{ref}} \). It is done in order to resample the selected data, lie in the \( i \)th selected window closer to the Nyquist frequency. It avoids the unnecessary interpolations during the data resampling process and so reduces the computational load of the proposed technique.

For the case, \( F_s' \leq F_{\text{ref}}, F_{s_i} \) is chosen as: \( F_{s_i} = F_s' \). In this case, it appears that the data lie in the \( i \)th selected window may be resampled at a frequency, which is less than the Nyquist frequency of \( x(t) \) and so it can cause aliasing. Since, the sampling rate of the AADC varies according to the slope of \( x(t) \) [2]. A high frequency signal part has a high slope and the AADC samples it at a higher rate and vice versa. Hence, a signal part with only low frequency components can be sampled by the AADC at a sub-Nyquist frequency of \( x(t) \). But still this signal part is locally over-sampled in time with respect to its local bandwidth [11, 13]. It is valid as far as \( \Delta x(t) = \Delta V_{\text{in}} \), because it makes the relevant signal part to cross all thresholds (more than one) of the AADC, so it is locally over-sampled in time. This statement is further illustrated with the results summarized in Table II. Hence, there is no danger of aliasing, when the low frequency relevant signal parts are locally over-sampled in time at overall sub-Nyquist frequencies.

D. Adaptive Resolution Analysis

The STFT is a classical tool, used for the time-frequency characterization of time varying signals [6]. The STFT of a sampled signal \( x_n \) is determined by computing the DFT (Discrete Fourier Transform) of an \( N \) samples segment centred on \( \tau \), which describes the spectral contents of \( x_n \) around the instant \( \tau \). Where, \( N \) is defined by Equation 15.

\[
N = L \cdot F_s. \quad (15)
\]

In Equation 15, \( L \) is the effective length in seconds of the window function \( w_n \) and \( F_s \) is the sampling frequency. The STFT can be expressed mathematically by Equation 16.

\[
X[\tau, f] = \sum_{n=-\frac{L}{2}}^{\frac{L}{2}} x_n w_{n-\tau} e^{-j2\pi f n}. \quad (16)
\]

In Equation 16, \( f \) is the frequency index, which is normalised with respect to \( F_s \).

\( L \) controls the STFT time and frequency resolution [6]. In the classical case, the input signal is sampled at a fixed sampling frequency \( F_s \), regardless of its local variations. Thus, a fixed \( L \) results into a fixed \( N \) (cf. Equation 15). In the case, when the spectrum of each windowed block is calculated with respect to \( \tau \) and no overlapping is performed between the consecutive blocks, then the time resolution \( \Delta \tau \) and the frequency resolution \( \Delta f \) of the STFT can be defined by Equations 17 and 18 respectively.

\[
\Delta \tau = L. \quad (17) \quad \Delta f = F_s / N. \quad (18)
\]

Equation 18 shows that for a fixed \( F_s \), \( \Delta f \) can be increased by increasing \( N \). But increasing \( N \) requires to increase \( L \) which will reduce \( \Delta \tau \) (cf. Equation 17). Thus, a larger \( L \) provides better \( \Delta f \) but poor \( \Delta \tau \) and vice versa. This conflict between \( \Delta f \) and \( \Delta \tau \) shows the limitation of the STFT, which is the reason for the creation of the MRA (multi resolution analysis) techniques [7, 14]. The MRA techniques provide a good frequency but a poor time resolution for the low-frequency events and a good time but a poor frequency resolution for the high-frequency events. It is the type of analysis, best suited for most of the real life signals [7].
In this article, the fixed resolution dilemma is resolved to a certain extent by revising the STFT. The proposed STFT is a smart alternative of the MRA techniques. It performs adaptive time-frequency resolution analysis, which is not attainable with the classical STFT. It is achieved by adapting the Fs, L and Nr according to the local variations of x(t). Thus, the time resolution $\Delta t$ and the frequency resolution $\Delta f$ of the proposed STFT can be specific for the $i^{th}$ selected window and are defined by Equations 19 and 20 respectively.

$$\Delta t = L \cdot \text{Eq}(19)$$

$$\Delta f = Fs / Nr \cdot \text{Eq}(20)$$

Because of this adaptive resolution, the proposed STFT will be named as the ARSTFT (adaptive resolution STFT), throughout the following parts of this article. This adaptive nature of the ARSTFT also leads towards a drastic computational gain, compared to the classical one. It is achieved firstly by avoiding the unnecessary samples to process and secondly by avoiding the use of the cosine window function as far as the condition 8 is true. The ARSTFT is defined by Equation 21.

$$X(t, f) = \sum_{n} \left[ \text{Re sample}(x(t_n)) \cdot e^{-j2\pi n f} \right]$$

Where, $t$ and $f$ are the central time and the frequency index of the $i^{th}$ selected window respectively, $f$ is normalised with respect to $Fs$, $n$ is the index of the resampled data points lie in the $i^{th}$ selected window. The notation $w_n$ represents that the window function length $L$ and shape (rectangle or cosine) can be adapted for the $i^{th}$ selected window.

IV. ILLUSTRATIVE EXAMPLE

In order to illustrate the ARSTFT an input signal $x(t)$, shown on the left part of Fig. 3 is employed. Its total duration is 30 seconds and it consists of four active parts. The summary of $x(t)$ activities is given in Table I.

<table>
<thead>
<tr>
<th>Activity</th>
<th>Signal Component</th>
<th>Length (Sec)</th>
</tr>
</thead>
<tbody>

<td>1.6</td>
</tr>
</tbody>
</table>

Table I shows that $x(t)$ is band limited between 50 to 500 Hz. In this example $x(t)$ is sampled by employing a 3-bit resolution AADC. Thus, $F_{\text{min}}$ and $F_{\text{max}}$ become 7 kHz and 0.7 kHz respectively (cf. Equations 6, 7). $F_{\text{ref}} = 1.25$ kHz is chosen, which satisfies the criteria given in Section III-C. $\Delta V_{in} = 1.8v$ is chosen, thus $q$ becomes 0.2571v in this case (cf. Equation 4).

The selected signal obtained with the EASA is shown on the right part of Fig. 3. By following the criteria given in Section III-B, $N_{\text{ref}} = 4096$ is chosen, which leads to 6 selected windows. First three selected windows correspond to the first three activities and the remaining corresponds to the fourth activity. The last three selected windows are not distinguishable on the right part of Fig. 3, because they lie consecutively on the fourth activity. The parameters of each selected window are summarised in Table II.

Table II exhibits the interesting features of the ARSTFT, which are achieved due to the smart combination of the non-uniform and the uniform signal processing tools. $Fs$ represents the sampling frequency adaptation by following the local variations of $x(t)$. $N_{\text{ref}}$ shows that the relevant signal parts are locally oversampled in time with respect to their local bandwidths. $Fr$ shows the adaptation of the resampling frequency for the $i^{th}$ selected window. It further adds to the computational gain of the ARSTFT, by avoiding the unnecessary interpolations during the resampling process. $N_{\text{ref}}$ shows that how the adjustment of $Fr$ avoids the processing of unnecessary samples during the spectral computation (cf. Equation 21). $L$ exhibits the dynamic feature of the EASA, which is to correlate the window function length with the local variations of $x(t)$. Adaptation of $L$, $Fs$ and $Nr$ leads to the adaptive time-frequency resolution of the ARSTFT, which is clear from the values of $\Delta t$ and $\Delta f$ in Table III.

Table III demonstrates that ARSTFT adapts its time-frequency resolution by following the local variations of $x(t)$. It provides a good frequency but a poor time resolution for the low frequency parts of $x(t)$ and vice versa. This type of analysis is best suited for most of the real life signals [7]. The spectrum of each selected window is computed and plotted with respect to $t_i$ on Fig. 4.

Fig. 4 shows the fundamental and the periodic spectrum peaks of each selected window. The adaptation of $Fr$ for the $i^{th}$ selected window can be visualised on Fig. 4. In this case, the spectrum periodic frequency $f_p$ is equal to $Fr$, for the $i^{th}$
selected window. As $F_x'$ and $F_x^s$ both remain less than $F_{ref}$, so
$F_{rs}' = F_x'$ and $F_{rs}^s = F_x^s$ are chosen. Contrary, $F_x'$ to $F_x^s$ all
become greater than $F_{ref}$, thus $F_{rs}'$ to $F_{rs}^s$, all are chosen
equal to $F_{ref}$ (cf. Table II).

The ARSTFT also adapts the window shape (rectangle or
cosine), for the $i^{th}$ selected window. The condition 8 remains
true for the first three selected windows, thus $D'$ is set to 0. As
no signal truncation occurs so no cosine window is required
in this case. On the other hand, the number of samples for the
fourth activity is 11200. Therefore, $N_{ref} = 4096$ leads to the
three selected windows for the time span of the fourth activity
of $x(t)$. The condition 8 becomes false, thus $D'$ is set to 1. As
signal truncation occurs, so suitable length cosine (Hanning)
windows are employed to reduce this truncation effect.

In the classical case, if $F_x = F_{ref}$ is chosen, in order to satisfy
the Nyquist sampling criterion for $x(t)$. Then the whole signal
will be sampled at 1.25 kHz, regardless of its local variations.
Moreover, the windowing process is not able to select only
the active parts of the sampled signal. In addition, $L$ remains
static and is not able to adapt with the local variations of $x(t)$.
This static nature makes the classical system to process un-
necessary samples and so causes an increased computational
activity than the proposed one. For this studied example, the
fixed $N=4096$, will lead to nine fixed $L=3.3$ second windows,
for the total $x(t)$ time span of 30 seconds. It leads to the fixed
$\Delta_T=3.3$ seconds and $\Delta_f=0.31$ Hz for all nine windows (cf.
Equations 17 and 18).

V. COMPUTATIONAL COMPLEXITY

This section compares the computational complexity of the
ARSSTFT with the classical STFT. The complexity evaluation
is made by considering the number of operations executed
to perform the algorithm.

In the classical case, the incoming signal is sampled at a
fixed sampling frequency, regardless of its local variations.
In this case, a time invariant, fixed $L$, cosine window function, is
employed to window the sampled data. If $N$ is the number of
samples lie in the window then the windowing operation will
perform $N$ multiplications between $w_n$ and $x_n$ (cf. Equation
16). The spectrum of the windowed data is obtained by com-
puting its DFT. A complex term is involved in the DFT com-
putation. The DFT complexity is calculated by taking the real
and the imaginary parts separately. Thus, DFT performs $2N$
multiplications and $2(N-1)$ additions per output frequency.
For larger values of $N$, $2(N-1)=2N$. Thus, the DFT computa-
tional complexity for $N$ output frequencies becomes $2N^2$
additions and $2N^2$ multiplications. The combine computa-
tional complexity $C_1$ of the STFT is given by Equation 22.

For the proposed ARSTFT, $F_x'$, $F_{rs}'$ and $w_n'$ are not fixed
and are adapted for the $i^{th}$ selected window, according to the
local variations of $x(t)$. In comparison to the classical case,
this approach locally requires some extra operations for each
selected window. The EASA performs $2N$ comparisons
and $N$ increments for the $i^{th}$ selected window (cf. Section III-B).
The choice of $F_{rs}'$ and window shape, require three compari-
sons. The selected signal is resampled before computing its
DFT. The NNRI is employed for the resampling purpose. The
NNRI only requires a comparison operation for each resam-
pled observation. Therefore, the resampler performs $N^2$
comparisons. If $D' = 1$, then a cosine window function is applied
on the resampled data, which performs $N^2$ multiplications
(cf. Fig. 2). The DFT performs $2(N^2)'$ additions and $2(N^2)'$
multiplications for the $i^{th}$ selected window. The combine computa-
tional complexity $C_2$ of the ARSTFT is given by
Equation 23.

\[
C_1 = A \left[ N + 2(N')^2 + 2(N')^2 \right] \quad (22) \\
C_2 = \sum_{i=1}^{N} \left[ N_i + 2N_i' + 3N_i'' + \alpha N_i' + 2(N_i')^2 + 2(N_i')^2 \right] \quad (23)
\]

In Equation 22, $A$ is the total number of windows, occurs
for the observation length of $x(t)$. In Equation 23, $i=1,2,...,K$
represents the index of the selected window. $\alpha$ is a multi-
plying factor, its value is 1 if $D' = 1$ and 0 if $D' = 0$. From $C_1$
and $C_2$ it is clear that there are uncommon operations between
both techniques. In order to make them approximately com-
parable the following assumption is made.

* An increment or a comparison has the same processing cost
as that of an addition.

By following this assumption, comparisons and increments
are merged into additions count, during the complexity
evaluation process. The computational comparison of the
ARSSTFT with the classical one is made for results of the il-
люстративное example. The gains are summarized in Table IV.

<table>
<thead>
<tr>
<th>Time Span (Sec)</th>
<th>Gain in Additions</th>
<th>Gain in Multiplications</th>
</tr>
</thead>
<tbody>
<tr>
<td>1st activity</td>
<td>2.737</td>
<td>2.739</td>
</tr>
<tr>
<td>2nd activity</td>
<td>212.473</td>
<td>214.021</td>
</tr>
<tr>
<td>3rd activity</td>
<td>42.686</td>
<td>42.955</td>
</tr>
<tr>
<td>4th activity</td>
<td>12.213</td>
<td>12.365</td>
</tr>
</tbody>
</table>

Table IV shows the gain in additions and multiplications of
the ARSTFT over the classical STFT for each $x(t)$ activity. It
shows that the ARSTFT leads to a significant reduction of the
total number of operations as compare to the classical STFT.
This reduction in operations is achieved by adapting $F_{x}'$, $F_{rs}'$
and $w_n'$ according to the local variations of $x(t)$.

VI. INTERPOLATION ERROR

The interpolated samples are calculated by employing the
level-crossing samples. For the practical AADC, there exist
uncertainties in the time-amplitude pairs of the level-crossing
samples [2]. These uncertainties accumulate in the interpola-
tion process and cause to increase the error [4]. Therefore, in
order to have a fair idea of the interpolation error the exact
time-amplitude pairs of the level-crossing samples are calcu-
lated by employing the method discussed in [12].

The mean interpolation error is calculated for each selected
window by employing Equation 14. The results are summa-
rized in Table V.

<table>
<thead>
<tr>
<th>Window</th>
<th>1°</th>
<th>2°</th>
<th>3°</th>
<th>4°</th>
<th>5°</th>
<th>6°</th>
</tr>
</thead>
<tbody>
<tr>
<td>Mle(dB)</td>
<td>-28.9</td>
<td>-28.4</td>
<td>-28.2</td>
<td>-26.1</td>
<td>-26.1</td>
<td>-25.4</td>
</tr>
</tbody>
</table>

Table V shows that the error introduced by the resampling
process is quite a minor one. In the case of high precision
applications, the resampling error can be further reduced by
increasing the AADC resolution $M$ and the interpolation or-
under [4, 11, 15]. Thus, an increased accuracy can be achieved at the cost of an increased computational load. Therefore, by making a suitable compromise between the accuracy level and the computational load, an appropriate solution can be devised for a given application.

VII. CONCLUSION

A new tool for the adaptive resolution time-frequency analysis has been proposed. The ARSTFT is especially well suited for the low activity sporadic signals like electrocardiogram, phonocardiogram, seismic signals, etc. It is shown that $F_r s$ and $F_{rs}$ change by following the $x(t)$ local variations. Criteria to choose the appropriate $F_{ref}$ and $N_{ref}$ are developed. A complete methodology of choosing $F_{rs}$ and $w_i$ for the $i^{th}$ selected window has been demonstrated. It is shown that the ARSTFT adapts its time-frequency resolution by following the local variations of $x(t)$. It provides a good time but a poor frequency resolution for the high-frequency parts of $x(t)$ and vice versa. This type of analysis is best suited for most of the real life signals [7]. The interpolation error is calculated. A higher accuracy can be achieved by increasing the AADC resolution and the interpolation order. Thus, a suitable solution can be proposed for a given application by making an appropriate trade off between the accuracy level and the computational load.

The ARSTFT outperforms the STFT. The first advantage of the ARSTFT over the STFT is the adaptive time-frequency resolution and the second one is the computational gain.

These smart features of the ARSTFT are achieved due to the joint benefits of the AADC, the EASA and the resampling, as they enable to adapt $F_r s$, $F_{rs}$, $N$, $N_r$ and $w_i$ by exploiting the local variations of $x(t)$.

The employment of fast algorithms in place of the DFT for the spectrum computation is in progress. It will add up to the computational gain of the ARSTFT. Performance comparison of the ARSTFT with the MRA techniques in terms of computational complexity and quality is an area of future research. Moreover the performance study of the ARSTFT for the real applications is a future task.
