FEA for Transient Responses of an S-Shaped Force Transducer with a Viscoelastic Absorber Using a Nonlinear Complex Spring

T. Yamaguchi, Y. Fujii, A. Takita and T. Kanai

Abstract—To compute dynamic characteristics of nonlinear viscoelastic springs with elastic structures having huge degree-of-freedom, Yamaguchi proposed a new fast numerical method using finite element method [1]-[2]. In this method, restoring forces of the springs are expressed using power series of their elongation. In the expression, nonlinear hysteresis damping is introduced. In this expression, nonlinear complex spring constants are introduced. Finite element for the nonlinear spring having complex coefficients is expressed and is connected to the elastic structures modeled by linear solid finite element. Further, to save computational time, the discrete equations in physical coordinate are transformed into the nonlinear ordinary coupled equations using normal coordinate corresponding to linear natural modes. In this report, the proposed method is applied to simulation for impact responses of a viscoelastic shock absorber with an elastic structure (an S-shaped structure) by colliding with a concentrated mass. The concentrated mass has initial velocities and collides with the shock absorber. Accelerations of the elastic structure and the concentrated mass are measured using strain gauges fabricated in the S-shaped portion as twin beams near the central hole as shown in Fig.2. These two beams play a role of a pair of parallel springs in y direction. When external load is applied in y direction, strains are measured using strain gauges fabricated in the S-shaped structure. Using the strains, forces $F_{\text{max}}$ of the transient responses are measured.

I. INTRODUCTION

To reduce impacts from precision instruments and so on, viscoelastic shock absorbers are used. These viscoelastic absorbers sometimes have nonlinearity between their restoring forces and deformations under relatively large load. Moreover, their restoring forces sometimes have nonlinearity in hysteresis. Therefore, it is of importance to clarify nonlinear dynamic properties of viscoelastic absorbers with elastic structures under impact load.

This paper deals with numerical analysis of impact responses for a viscoelastic shock absorber connected with an elastic structure (an S-shaped structure) using a fast finite element method proposed by Yamaguchi [1]-[2]. In this analysis, the viscoelastic absorber is modeled by using a nonlinear complex spring. The restoring force of the spring is expressed as power series of its elongation. The restoring force also includes nonlinear hysteresis damping. Therefore, complex spring constants are introduced for not only the linear component but also nonlinear components of the restoring force. Finite element for the nonlinear complex spring is expressed and is connected to an elastic structure modeled by linear solid finite elements.

The discrete equations of this system in physical coordinate are transformed into the nonlinear ordinary coupled equations using normal coordinate corresponding to linear natural modes. The transformed equations are integrated numerically in extremely small degree-of-freedom.

In this paper, we apply our proposed FEM to examine dynamic errors in an S-shaped force transducer when transient responses of a viscoelastic shock absorber are measured. The transient responses are obtained when a concentrated mass (i.e., a rigid levitated block) is collided with the absorber. The elastic structure in this study is an S-shaped structure, which is a part of the force transducer as shown in Fig.1.

To investigate the dynamic errors in the transducer, the reference force is measured using Levitation Mass Method proposed by Fujii [3]. The experimental dynamic errors [3] are compared with the calculated ones from our proposed FEM.

II. EXPERIMENTAL SYSTEM [3]

Fig. 1 shows the outline of the experimental system carried out by Fujii [3]. To evaluate mechanical responses of a viscoelastic shock absorber, an S-shaped force transducer is connected with the absorber. A mass levitated by linear pneumatic bearing is collided with the absorber in y direction, and transient responses are measured using the force transducer. The S-shaped structure in the force transducer has two thin portions as twin beams near the central hole as shown in Fig.2. These two beams play a role of a pair of parallel springs in y direction. When external load is applied in y direction, strains are measured using strain gauges fabricated in the S-shaped structure. Using the strains, forces $F_{\text{max}}$ of the transient responses are measured.

To verify precision of the measured force $F_{\text{max}}$, Fujii also measured the velocity $v_1$ of the levitated mass using an interferometer as shown in Fig.1. By differentiating the measured velocity $v_1$, acceleration $a_1$ of the levitated mass is obtained. Further, the reference force $F_{\text{max}} = M a_1$ is identified.
using the acceleration $a_i$ and mass $M_i = 2.6526\,kg$ of the levitated mass. Fujii compared between the reference force $F_{max}$ and the force $F_{trans}$ obtained from the S-shaped transducer as shown in Fig. 3. And he showed that there exist small dynamic errors in the measured force $F_{trans}$ of the S-shaped force transducer. Fig. 4 shows a time history of the discrepancy $\Delta F = F_{trans} - F_{max}$ between the measured force $F_{trans}$ by the transducer and the reference force $F_{max}$. Further, Fujii found out that the discrepancy $\Delta F = F_{trans} - F_{max}$ corresponds to the force calculated by $M_2 a_2$. $a_2$ is the acceleration of the S-shaped structure and $M_2$ is the half of the mass for the S-shaped structure. Using $\Delta F = M_2 a_2$, Fujii proposed a correction method of the measured force $F_{trans}$. To obtain correction force $\Delta F$, he added an accelerometer to the S-shaped structure as shown Fig. 1. The measured acceleration $a_2$ is utilized to correct the measured force $F_{trans}$ in real time.

In this paper, to investigate the correction force $\Delta F$ (i.e. the discrepancy between $F_{trans}$ and $F_{max}$) in detail, numerical simulations for this experimental system are performed.

We also use the experimental results to verify our proposed numerical method using FEA (i.e. Finite Element Analysis) with a nonlinear complex spring.

The detail conditions of this experimental system are added as follows. The experimental system has the levitated mass (i.e.
a levitated rigid block), which can smoothly travel along a guide way in y direction due to a pneumatic linear bearing as shown in Fig.1. The block is levitated due to air film (thickness is 8 (μm)) at the interfaces between the block and the guide. Pressure at the interfaces is self-controlled by orifice effect to maintain the thickness of the air film. Owing to this system, the block can move toward the y-direction under extremely low friction. An extension rod is connected with the levitated mass. These parts have a role of moving parts with initial velocity \( v_0 \) given by a hand. The moving parts collide with the small strip of the viscoelastic shock absorber attached with one end of the S-shaped structure. This experimental system is proposed and named as Levitation Mass method by Fujii [4]-[6]. In the vicinity of this end of the transducer, the accelerometer is fabricated. Another end of the transducer is fixed on the rigid base. A gel is filled in the central hole of the S-shaped structure to obtain damping effect as shown in Fig.2.

### III. NUMERICAL PROCEDURE

Fig. 5 represents the FEM model for the S-shaped structure in the force transducer to evaluate. In this figure, the S-shaped structure is modeled as an elastic body using finite elements, and the levitated mass is modeled by a concentrated mass. The viscoelastic shock absorber is modeled by a nonlinear spring with nonlinear damping. Origin of this model is set on the position where the levitated mass begins to contact with the viscoelastic absorber. An initial velocity \( v_0 = -180 \) (mm/sec) in y-direction is given to the concentrated mass (i.e. the levitated mass).

#### A. Discretized Equation for the Viscoelastic Absorber

A small strip of the viscoelastic absorber is modeled by using a concentrated nonlinear spring with nonlinear hysteresis. To represent the nonlinear hysteresis, we propose to introduce a nonlinear complex spring. As shown in Fig.5, it is assumed that the nonlinear complex spring with viscoelasticity has principal elastic axis in y direction. We denote displacement as \( U_y \) at the interfaces between the block and the guide. Hence, we also create the three dimensional finite elements for the gel as depicted in Fig.5. Viscoelasticity of the gel is taken into account using complex modulus of elasticity \( \gamma_{\text{gel}} \) and \( \eta_{\text{gel}} \). These parts have a role of moving parts with initial velocity 0 \( \gamma \) in the same manner.

#### B. Discretized Equations of the S-Shaped Force Transducer Filled with the Gel

We assumed that equations of motion for the elastic structure of the S-shaped force transducer are expressed under infinitesimal deformation using a conventional three dimensional finite element method. To add damping effects, a viscoelastic gel is filled in the central hole of the force transducer as shown in Fig.2. Thus, we also create the three dimensional finite elements for the gel as depicted in Fig.5. Viscoelasticity of the gel is taken into account using complex modulus of elasticity \( E_g \) and \( \eta_g \). The real part \( E_g \) of the \( E_g \) stands for storage modulus of elasticity while \( \eta_g \) is material loss factor of the gel. For the transducer made by aluminum, complex modulus of elasticity \( E_g \) is also considered. By superposing all elements related to the S-shaped transducer and the gel, the following equations are obtained.

\[
[M_g] \ddot{u}_g + [K_g] u_g = \{f_g\}
\]
where, \([M_i], [K_i], \{f_i\} \) and \(\{u_i\}\) are mass matrix, complex stiffness matrix, nodal force vector and displacement vector for the S-shaped transducer and the gel, respectively. Isoparametric hexahedral elements with non-conforming modes are mainly used for the three dimensional finite elements.

C. Discrete Equation for Combined System between the S-Shaped Force Transducer with the Gel and the Viscoelastic Absorber with the Levitated Block

The restoring force \(\{r_i\}\) in Eq. (1) is added to the nodal force at the ends of the nonlinear complex spring on the nodes \(\alpha \) and \(\beta\). On the nodes \(\alpha\), the nonlinear complex spring (i.e. the viscoelastic absorber) is connected with the S-shaped force transducer. On the node \(\beta\), the spring is attached with the levitated mass modeled as a concentrated mass. And then the following expression in global system can be obtained:

\[
[M]\{\ddot{u}\} + [K]\{u\} + \{d\} = \{f\}
\]

(3)

where, \(\{u\}, [M], [K]\) and \(\{f\}\) are displacement vector, mass matrix, complex stiffness matrix and external force vector in global system, respectively. \(\{\ddot{u}\}\) is modified from \(\{\dot{u}\}\) to have the identical vector size to degree-of-freedom of the Eq.(3).

D. Approximate Computation of Modal Damping

To calculate linear modal damping (i.e. modal loss factor), we consider the following complex eigenvalue problem by neglecting the terms of the non-linear restoring force and the strain energy of each element \(e\), share \(S_{\phi}^{(e)}\) of strain energy of each element to total strain energy. The parameter \(\eta_{\phi} S_{\phi}^{(e)}\) corresponds to damping contribution of each element \(e\) to the entire system.

E. Conversion from the Discretized Equation in Physical Coordinate to the Nonlinear Equation in Normal Coordinate

It takes huge amount of computational time to calculate Eq.(3) in physical coordinate, directly. In this section, a numerical manipulation is proposed to decrease the degree-of-freedom for the discretized equations of motion.

First, we assume that linear natural modes \(\{\phi_{(i)}^{(e)}\}\) of vibration can be approximated to \(\{\phi_{(i)}^{(0)}\}\). Next, by introducing normal coordinates \(\tilde{b}_i\) corresponding to the linear natural modes \(\{\phi_{(i)}^{(0)}\}\), the nodal displacement vector can be expressed using both \(\{\phi_{(i)}^{(0)}\}\) and \(\tilde{b}_i\) as follows.

\[
\{u\} = \sum_i \tilde{b}_i \{\phi_{(i)}^{(0)}\}_0
\]

(10)

By substitution of Eq.(10) into Eq.(3), the following nonlinear ordinary simultaneous equations as to normal coordinates \(\tilde{b}_i\) can be obtained as:

\[
\begin{align*}
\tilde{b}_i & = \{\phi_{(i)}^{(0)}\}_0 + (\{\phi_{(i)}^{(0)}\}_0 + \{\phi_{(i1)}\}_0 + \{\phi_{(i2)}\}_0 + \ldots + \{\phi_{(ine)}\}_0 + \ldots) + \{\phi_{(i)}^{(e)}\}_0 + \{\phi_{(i1)}^{(e)}\}_0 + \{\phi_{(i2)}^{(e)}\}_0 + \ldots + \{\phi_{(ine)}^{(e)}\}_0 + \ldots
\end{align*}
\]

(11)

In Eq.(11), \(\omega_{0}\) represents the i-th natural frequency. \(\eta_{\phi}^{(e)}\) is the i-th modal loss factor. Since Eq.(11) has much smaller degree-of-freedom than that of Eq.(3), we can save computational time drastically. In Eq.(11), subscript \(t\) following a comma stands for partial differentiation with respect to time \(t\). \(\phi_{(i)}^{(e)}\) is the y-component of the eigenmode \(\{\phi_{(i)}^{(0)}\}_0\) at the connected node \(\alpha\) between the S-shaped force transducer and the viscoelastic shock absorber.
**F. Nonlinear Impact Response**

We give an initial velocity to the levitated mass connected with the viscoelastic shock absorber. And nonlinear impact responses of the S-shaped force transducer with the viscoelastic absorber are calculated by applying Runge-Kutta-Gill method to Eq.(11).

**IV. NUMERICAL RESULTS AND DISCUSSION**

**A. Verification of the Proposed Numerical Method**

First, we verify our proposed numerical method using Finite Element Analysis with nonlinear complex spring. Fig.6 shows time histories of the measured and calculated reference forces $F_{\text{ref}}$ using the levitated mass. These reference forces are obtained by $F_{\text{ref}} = M_1a_1$, where $a_1$ is the measured or calculated acceleration. In this graph, the origin of time is set when the levitated mass begins to collide with the viscoelastic shock absorber connected with the S-shaped structure. From Fig.6, the calculated reference force is consistent with the measured one. We can say that the reference force can be simulated using our proposed FEA for the transient response of the viscoelastic shock absorber.

Next, we compute dynamic errors of the S-shaped force transducer. Fujii found out in the previous paper [3] that the dynamic errors $F_{\Delta}$ of the transducer have relationship as $F_{\Delta} \cong M_2a_2$. $a_2$ is the measured acceleration from the accelerometer fabricated on the S-shaped structure. And $M_2$ is the half of the mass for the S-shaped structure. Therefore, to investigate the dynamic errors, we simulate the acceleration $a_2$ on the S-shaped structure.

Fig. 7 (b) shows the calculated time history of the acceleration $a_2$ for the S-shaped structure in comparison with an experimental one in Fig.7 (a). As illustrated in Fig. 8:
The calculated curve in Fig. 7 (b) using nonlinear complex spring for the viscoelastic shock absorber is consistent with experimental data in Fig. 7 (a). In Fig. 7, we can find two typical periods both in the experimental and calculated accelerations at the S-shaped structure. The short period 0.0025 (s) corresponds to the eigen frequency of the elastic mode for the S-shaped structure in \( y \)-direction as shown in Fig. 8.

Fig. 9 Comparison of the velocity at the S-shaped structure between calculated data and measured data [3]

As can be seen this figure, a half part of the S-shaped structure moves in this eigenmode, while the other half part of the S-shaped structure is at rest. Therefore, in this mode, the dynamic motion of the half part for the S-shaped structure is dominant. This fact leads that the correction method proposed by Fujii [3] using the acceleration \( a_2 \) and the half mass \( M_o \) of the S-shaped structure is proper.

The long period 0.013 (s) is related with the subharmonic component of order 1/7 for this elastic mode. Moreover, the long period is also related with the superharmonic component of order seven for the translation mode of the concentrated mass (i.e. the levitated mass) in \( y \)-direction. These relations can be regarded as internal resonance. This is caused by the nonlinearity of the viscoelastic shock absorber.

Additionally, Fig.9 shows the measured and calculated velocities at the S-shaped structure. Both results also agree well.

B. Effect of Material Properties for Gel on Dynamic Errors of S-Shaped Force Transducer

Next, we investigate influences of the material properties of the gel filled in the central hole on the dynamic errors of the S-shaped structure. For the previous simulations in Figs. 6-9, we use the material loss factor \( \eta_g = 0.700 \) (-) and the storage modulus of elasticity \( E_g = 0.00400 \) (GPa) for the gel. Under this condition, we obtain the modal loss factor \( \eta_{_{\text{tot}}}^{(i)} \) for the dominant eigen mode on the dynamic errors (i.e. the elastic mode of the S-shaped structure in \( y \)-direction) as shown in Fig. 8. According to Eq. (9), to increase modal damping \( \eta_{_{\text{tot}}}^{(i)} \) using the gel, we have to increase not only the material loss factor \( \eta_g \) of the gel but also the share of the strain energy of the gel to the total strain energy in this system.

Fig. 10 Effects of elasticity \( E_g \) of the gel on modal loss factors \( \eta_{_{\text{tot}}}^{(i)} \)

Fig. 11 Effects of elasticity \( E_g \) of the gel on dynamic errors of the force transducer

Fig. 12 Effects of elasticity \( E_g \) of the gel on the reference force

Fig.10 shows the relation between the modal loss factors \( \eta_{_{\text{tot}}}^{(i)} \) in this system and the storage modulus of elasticity \( E_g \) for the gel. In this graph, the constant value \( \eta_g = 0.700 \) (-) is given for the material loss factor of the gel. Thus, the change of the modal loss factor \( \eta_{_{\text{tot}}}^{(i)} \) in Fig.10 is caused by the change of the share of
the strain energy in the gel. As shown in Fig.10, the modal loss factor $\eta_{tot}^{(i)}$ has the local maximum value $\eta_{tot}^{(i)}=0.318$ (-) near $E_g=0.0900$ (GPa). Using the local maximum value, we compute a time history of the acceleration $a_2$ for the S-shaped structure as shown in Fig.11. The component of the short period for the mode decreases due to the increment of $\eta_{tot}^{(i)}$. This leads to less dynamic errors $\Delta F$ in the measured force using the force transducer. Fig.12 shows changes of the reference forces $F_{max}$ due to change of the modal loss factor from the initial value $\eta_{tot}^{(i)}=0.0496$ (-) to the local maximum value $\eta_{tot}^{(i)}=0.318$ (-). There exist significant changes of the reference force due to the increase of the storage modulus of elasticity $E_g$ for the gel. Therefore, the measured force using the force transducer is affected if we give too large storage modulus of elasticity $E_g$ for the gel. Thus, this result reveals that it is undesirable to use too large storage modulus of elasticity $E_g$ for precision measurement of the force, even though we obtain less dynamic errors due to the elastic mode in the S-shaped transducer.

Fig.13 shows time histories of the reference force $F_{max}$ when the storage modulus of elasticity $E_g$ changes from $E_g=0.00100$ (GPa) to 0.00900 (GPa). These values of $E_g$ are less than the maximal value $E_g=0.0900$ (GPa) in Fig.12. The corresponding modal loss factor $\eta_{tot}^{(i)}$ changes from $\eta_{tot}^{(i)}=0.0277$ (-) to $\eta_{tot}^{(i)}=0.0928$ (-) as $E_g$ increases. As shown in Fig.13, the curves of the reference force $F_{max}$ never change under this condition. From these results, there are no influences on the reference force when the storage modulus of elasticity for the gel is less than 0.00900 (GPa). Using the same conditions for the storage modulus of elasticity $E_g$, we also compute the time histories of acceleration $a_2$ for the S-shaped structure as shown in Fig.14. The acceleration $a_2$ decreases as $E_g$ increases from $E_g=0.00100$ (GPa) to 0.00900 (GPa). From these results, it is possible to reduce the dynamic errors due to the acceleration $a_2$ of the S-shaped structure without influences on the reference force $F_{max}$, when we set the storage modulus of elasticity $E_g=0.00900$ (GPa) for the gel.

On the other hand, the modal loss factors $\eta_{tot}^{(i)}$ are also written in Fig.10 for the mode related with the long period in the dynamic errors in Fig.7. As shown in Fig.10, $\eta_{tot}^{(i)}$ for this mode (i.e. the mode of the levitated mass and the spring of the absorber) maintains a constant value, though the storage modulus of elasticity changes. The constant value corresponds to the material loss factor $\eta_s=0.300$ for the viscoelastic shock absorber. Thus, there are small influences of storage modulus of elasticity $E_g$ on these modal loss factors $\eta_{tot}^{(i)}$ for this mode.

This implies that effects of the gel are small on the component of the long period in dynamic errors.

According to Eq. (9), the modal loss factor $\eta_{tot}^{(i)}$ also increases as the material loss factor $\eta_l$ of the gel increases.

![Fig. 14 Effects of elasticity $E_g$ of the gel on dynamic errors of the force transducer](image1.png)

![Fig. 15 Effects of material loss factor $\eta_l$ of the gel on the reference force $F_{max}$](image2.png)

![Fig. 16 Effects of material loss factor $\eta_l$ of the gel on dynamic errors of the force transducer](image3.png)
When the material loss factor $\eta_g$ of the gel changes from $\eta_g = 0.0100 (-)$ to $\eta_g = 0.700 (-)$ under the constant storage modulus of elasticity $E_g = 0.00400$ (GPa), Figs. 15 and 16 show the calculated reference force $F_{max}$ and the calculated acceleration $a_z$ of the S-shaped structure (i.e. dynamic error), respectively. The corresponding modal loss factor $\eta_{tot}^{(i)}$ changes from $\eta_{tot}^{(i)} = 0.0144 (-)$ to $\eta_{tot}^{(i)} = 0.0496 (-)$. As shown in Fig.16, the dynamic error decreases as the material loss factor $\eta_g$ of the gel increases. On the other hand, the reference force $F_{max}$ does not change though the material loss factor $\eta_g$ of the gel increases as shown in Fig.15. These results imply that the material loss factor $\eta_g$ of the gel can reduce the dynamic error of the force transducer without the influences on the reference force $F_{max}$.

V. CONCLUSION

By applying the numerical method proposed by Yamaguchi, simulation was carried out for impact responses of a viscoelastic shock absorber with an S-shaped elastic structure. This fast computational method using nonlinear finite element method is aimed for nonlinear impact responses of elastic structures connected with nonlinear concentrated springs with nonlinear hysteresis.

The restoring force of the spring is assumed to express as power series of elongation with nonlinear hysteresis damping. In this expression, nonlinear complex spring constants are introduced. Finite element for the nonlinear complex spring is expressed and is connected to elastic structures modeled by linear solid finite elements. Further, the discretized equations in physical coordinate are transformed into the nonlinear ordinary coupled equations using normal coordinate corresponding to linear natural modes. The transformed equations were integrated numerically. This transformation can save computational time drastically.

In this report, the proposed method is applied to simulation for impact responses of a viscoelastic shock absorber with an elastic structure (an S-shaped structure) by colliding with a concentrated mass. The concentrated mass has initial velocities and collides with the shock absorber. Accelerations of the elastic structure and the concentrated mass are measured using Levitation Mass Method proposed by Fujii [3]. The calculated accelerations from the proposed FEM, corresponds to the experimental ones.

Moreover, using this method, we also investigate dynamic errors of the S-shaped force transducer due to elastic mode in the S-shaped structure.
