Automatic Generation Control of an Interconnected Power System with Capacitive Energy Storage

Rajesh Joseph Abraham, D. Das and Amit Patra

Abstract—This paper is concerned with the application of small rating Capacitive Energy Storage units for the improvement of Automatic Generation Control of a multiunit multiarea power system. Generation Rate Constraints are also considered in the investigations. Integral Squared Error technique is used to obtain the optimal integral gain settings by minimizing a quadratic performance index. Simulation studies reveal that with CES units, the deviations in area frequencies and inter-area tie-power are considerably improved in terms of peak deviations and settling time as compared to that obtained without CES units.

Keywords—Automatic Generation Control, Capacitive Energy Storage, Integral Squared Error.

I. INTRODUCTION

Electrical power generation and consumption should perfectly go hand-in-hand if an electric energy system is to be strictly maintained in its nominal state characterized by nominal frequency, voltage profile and load flow configuration. But because of the random nature of the power demands, this power generation-consumption equilibrium, in reality, cannot be strictly met. Thus, a power deviation occurs. This imbalance, causes a deviation of system frequency and tie-power from their scheduled values. To bring back the frequency and tie-power to their respective scheduled values, most of the utilities prefer to use integral or proportional-integral controllers in their system.

Different energy storage technologies such as pumped hydro, compressed air, fuel cells, batteries, Superconducting Magnetic Energy Storage (SMES), flywheels etc have been developed, investigated and explored to meet wide ranging needs. However, most of these technologies store electrical energy in other forms in addition to their own inherent disadvantages as pointed out by [1] – [2]. Capacitors can store electrical energy directly in their electric field by accumulating electrostatic charges on the two parallel plates. Reference [3] has shown that the relative merits of Capacitive Energy Storage (CES) which outweigh Superconducting Magnetic Energy Storage (SMES), their magnetic counterparts are (1) CES at room temperatures or with cryogenic hypercapacitors (CHC) at 77 K eliminate the high operating costs of cryogenic refrigerators for liquid helium (4.2 K) in SMES. Hence, the effective energy efficiency is more and close to 100% for CES, the only losses being energy loss due to Joule heating in the electrodes and to internal leakage currents and self-discharge (2) CES has relatively higher energy density and smaller footprint and lower weight in contrast to SMES of the same storage capacity (3) CES can be upgraded by adding additional capacitor modules to increase capacity whereas an SMES coil cannot be so upgraded (4) There are no stray magnetic fields unlike in SMES. The electric fields within capacitors are entirely contained within the enclosure (5) There are no large forces in CES whereas; SMES coils develop strong internal Lorentz forces during discharge. These forces arise from the interactions between the currents and the magnetic field. But, the magnitude of forces from charge-field interactions in capacitors is smaller and force-related failures in capacitors are virtually unknown (6) SMES deliver high power rates but at the cost of high voltages. To withdraw energy from the circulating current, a voltage across the superconducting coil is generated by switching. For fast discharges and large power rates, very large voltages may be involved, which increases the risks of large voltage gradients within the coil and hence, turn-to-turn voltage breakdown. Capacitors are intrinsically "open circuits" to DC so that the only failure mode possible is a short circuit caused by voltage breakdown. When a CHC in a bank suffers a voltage failure, the current path is instantly burn out by the large momentary currents. This gives CES a self-protecting property that is absent in other energy storage systems. Hence, CHC energy storage systems are expected to be robust, have extremely low failure rates, and are fault tolerant. Further, no thermal shock failures have ever been observed for CES. Thus, their ruggedness for practical applications is assured. (7) CES involves lower initial costs. Preliminary estimates indicate that equivalent energy storage in a CES involves an initial cost 40-50% less than that for SMES. In light of this, Capacitive Energy Storage (CES) systems may be an alternative for improving the performance of interconnected power system and either supercapacitors or
CHC can be used for storage purposes in CES.

The AGC with a CES unit, has been studied in [4] but, that of a standalone power system.

In view of the above, the main objectives of the present work are:
(1) To study the effect of CES units on AGC of multiunit multiarea power system considering GRC
(2) To find out a suitable error signal to the CES control logic.
(3) To optimize the integral gain settings using Integral Square Error (ISE) technique by minimizing a quadratic performance index without and with CES units in the presence of GRCs.
(4) To compare the dynamic responses without and with CES units.

II. SYSTEM INVESTIGATED

Since the system under consideration is exposed to a small change in load during its normal operation, a linearized model is sufficient for its dynamic representation. Fig. 1 shows the small perturbation transfer function block diagram model of the two-area power system.

The nominal parameters of the power system as well as the CES units are given in the Appendix. Area 1 consists of two reheat units and area 2 consists of two non-reheat units. Because of the thermodynamic and mechanical constraints, there is a limit to the rate at which the output power of steam turbines can be changed. This limit is referred to as Generator Rate Constraint (GRC). For the present study, a GRC of 3% per min. for reheat units and 10% per min. for nonreheat units have been considered for each unit in areas 1 and 2 respectively as in [5]. apf11 and apf12 are the ACE participation factors in area 1 and apf21 and apf22 are the ACE participation factors in area 2. Note that apf11 + apf12 = 1.0 and apf21 + apf22 = 1.0. A small rating CES unit of 3.8 MJ storage capacity is fitted to both the areas 1 and 2 to examine its effect on the power system performance. A step load disturbance of 1% of nominal loading has been considered for the investigation. The control signal to the CES unit can be frequency deviation or the Area Control Error (ACE). In this paper, both the cases are studied.

Since the power system model considered is a linear continuous-time dynamic system, it can be represented by the standard state space model as:

$$\dot{X} = AX + BU + \Gamma p$$

where X, U and p are the state, control and disturbance vectors respectively and A, B and \(\Gamma\) are constant matrices of compatible dimensions associated with them. For the system considered, the state, control and disturbance vectors are respectively given as

$$X^T = [\Delta f_1 \Delta f_2 \Delta P_{tie 12} \Delta P_{g1} \Delta P_{g2} \Delta P_{g3} \Delta P_{g4} \Delta P_{r1} \Delta P_{r2} \Delta P_{r3} \Delta P_{r4} \Delta E_{d1} \Delta E_{d2} \Delta \Delta ]$$

$$U^T = [U_1, U_2]$$ and $$p^T = [\Delta P_{d1}, \Delta P_{d2}]$$

III. CAPACITIVE ENERGY STORAGE

A Capacitive Energy Storage (CES) consists of, from circuit point of view, a supercapacitor or a cryogenic hypercapacitor (CHC), a Power Conversion System (PCS) and the associated protective circuitry as shown in Fig. 2. CHCs differ from the conventional capacitors in that they are multilayer ceramic capacitors with a dielectric that has its peak dielectric constant at 77 K, the temperature of liquid nitrogen. The dimensions of the capacitor are determined by the energy storage capacity required. The storage capacitor C may consists of many discrete capacitance units connected in parallel. The resistor \(R_1\) connected in parallel across the capacitor is the lumped equivalent resistance representing the dielectric and leakage losses of the capacitor bank. The PCS, consisting of an ac-to-dc rectifier and a dc-to-ac inverter, form the electrical interface between the capacitor and the power system. Two bridges are preferred so that harmonics produced on the ac bus and in the output voltage to the capacitor are reduced. The bypass thyristors provide a path for current \(I_1\) in the event of a
converter failure. The dc breaker allows current $I_d$ to be diverted into the energy dump resistor $R_D$ if the converter fails. Assuming the losses to be negligible, the bridge voltage $E_d$ is given by [6]

$$E_d = 2E_{d0}\cos\alpha - 2I_dR_D$$  \hspace{1cm} (2)

By changing the relative phase angle $\alpha$ of this pulse through a range of $0^\circ$ to $180^\circ$, the voltage across the capacitor, $E_d$ can be made to vary from its maximum positive value to the maximum negative value.

The voltage pulses from the firing circuits are timed to cause each SCR to begin conduction at a prescribed time. The sequence maintains a constant average voltage across the capacitor. The exact timing of the firing pulses relative to the phase of 50 Hz ac voltage determines the average dc voltage across the capacitor. Since the bridges always maintain unidirectional current and $E_d$ is uniquely defined by $\alpha$ for positive and negative values, the power flow $P_d$ in the capacitor is uniquely determined by $\alpha$ in both magnitude and direction. Thus, without any switching operation, reversibility as well as magnitude control of the power flow is achieved by continuously controlling the firing angle $\alpha$. The firing angle of the converter is controlled by an algorithm determined by utility needs, but basically the control circuit responds to a demand signal for a certain power level, either positive or negative. Then based on the voltage across the capacitor, a firing angle is calculated and transmitted to the firing circuit. The response time of the control and firing circuits to a new demand signal are so short that a new firing angle may be chosen for the very next SCR to be pulsed, say within a few milliseconds. This rapid response to power demands that may vary by hundreds of megawatts is a unique capability of CES relative to other energy storage systems such as pumped hydro, compressed air, flywheels etc. This ability to respond quickly allows the CES unit to function not only as an energy storage unit but also as a spinning reserve and to provide quick in service. When there is a sudden rise in load demand, the stored energy is almost immediately released through the PCS to the grid as pulsed AC. As the governor and other control mechanisms start working to set the power system to the new equilibrium condition, the capacitor charges to its initial value of voltage $E_{d0}$. The action during sudden releases of load is similar. The capacitor immediately gets charged towards its full value, thus absorbing some portion of the excess energy in the system, and as the system returns to its steady state, the excess energy absorbed is released and the capacitor voltage attains its normal value.

The power flow into the capacitor at any instant is $P_d = E_dI_d$ and the initial power flow into the capacitor is $P_{d0} = E_{d0}I_{d0}$ where $E_{d0}$ and $I_{d0}$ are the magnitudes of voltage and current prior to the load disturbance. When a load disturbance occurs, the power flow into the coil is

$$P_{d0} + \Delta P_d = (E_{d0} + \Delta E_d)(I_{d0} + \Delta I_d)$$  \hspace{1cm} (5)

so that the incremental power change in the capacitor is

$$\Delta P_d = (I_{d0}\Delta E_d + \Delta E_dI_{d0})$$  \hspace{1cm} (6)

The term $E_{d0}I_{d0}$ is neglected since $E_{d0} = 0$ in the storage mode to hold the rated voltage at constant value.

IV. CES BLOCK DIAGRAM REPRESENTATION

The set value of the CES voltage has to be restored at the earliest, after a load disturbance so that the CES unit is ready to act for the next load disturbance. For this, the capacitor voltage deviation can be sensed and used as a negative feedback signal in the CES control loop so that fast restoration of the voltage is achieved as shown in Fig. 3.
V. CES CONTROL LOGIC

Either frequency deviation or Area Control Error (ACE) can be used as the control signal to the CES unit (Δerror, = Δf, or ACE). E_{di} is then continuously controlled in accordance with this control signal. For the ith area, if the frequency deviation Δf_i (i.e., Δerror, = Δf_i), or any of the other areas, then the optimum gain settings can be obtained on an individual basis by considering the other area different in each area, then, the optimum gain settings can be obtained. It is proposed in [7] that, if the types of units are the same for obtaining the optimum values of integral gain settings of the two-area interconnected power system is also obtained by keeping the other area uncontrolled. In the present work, the optimum values of integral gain settings of the two-area interconnected power system is also obtained by keeping the other area uncontrolled. For different combinations of ACE participation factors, the optimal integral gains obtained using ISE technique by minimising the above quadratic performance index without and with CES units in the presence of GRCs, have been tabulated as shown in Tables 1 and 2 for areas 1 and 2 respectively.

VII. SIMULATION RESULTS

The responses of the two-area interconnected system have been studied in detail. Fig. 4 shows the dynamic responses for voltage and tie-line power deviations and Fig. 5 shows the generation responses for 1% step load disturbance in area 1 considering apf₁₁ = apf₁₂ = 0.5 and apf₂₁ = apf₂₂ = 0.5 without CES units and with CES units having Δf₁ as well as ACE₁ as the control signal. From Figs. 4 and 5, it is evident that the dynamic responses have improved significantly with the use of CES units. It can be observed that with the use of Δf₁ feedback to the CES control logic, the dynamic responses are better than those obtained with ACE₁ feedback and far improved than that without CES units.

As the load disturbance has occurred in area 1, at steady state, the power generated by generating units in area 1 are in proportion to the ACE participation factors. Therefore, as in Fig. 5, at steady state, ΔP₁₁ss = ΔP₁₁ × apf₁₁ = 0.01 × 0.5 = 0.005 p.u. MW and ΔP₁₂ss = ΔP₁₂ × apf₁₂ = 0.01 × 0.5 = 0.005 p.u. MW. Similarly, ΔP₂₁ss = ΔP₂₁ × apf₂₁ = 0.01 × 0.5 = 0.005 p.u. MW and ΔP₂₂ss = ΔP₂₂ × apf₂₂ = 0.01 × 0.5 = 0.005 p.u. MW at steady state.

Similar findings are also observed for 1% step load disturbance in area 2 as in Figs. 6 and 7.
VIII. CONCLUSIONS

In this paper, the responses of a two-area interconnected thermal power system with reheat and non reheat units have been studied considering generation rate constraints and integral gain settings have been optimized by Integral Squared Error (ISE) technique. The optimal integral gain settings with CES units are found to be higher than those without CES units. Small rating Capacitive Energy Storage units are fitted to both the areas and responses show that they are capable of consuming the oscillations in area frequency deviations and tie-line power deviations of the power system. Further, CES units reduce the settling time of the responses. Two different control logic for CES units are attempted and it was found that, the dynamic responses with frequency feedback to CES are better than that obtained with ACE feedback to CES units and far superior than that without CES units. Hence, it may be concluded that CES units are efficient and effective for improving the dynamic performance of AGC of interconnected power systems.

APPENDIX

(A) Capacitive Energy Storage Data
\[ K_{vd} = 0.1 \text{ kV/kA}, \quad K_{G} = 70 \text{ kV/Hz}, \quad T_{DC} = 0.05 \text{ s}, \quad C = 1 \text{ F}, \quad R = 1000 \Omega, \quad E_{d0} = 2 \text{ kV} \]

(B) System Data
\[ P_{R1} = P_{R2} = 1200 \text{ MW}, \quad T_{P1} = T_{P2} = 20 \text{ s} \]
\[ K_{P1} = K_{P2} = 120 \text{ Hz/p.u. MW}, \quad T_{R1} = T_{R2} = 10 \text{ s} \]
\[ K_{R1} = K_{R2} = 0.5, \quad T_{T1} = T_{T2} = T_{T3} = T_{T4} = 0.3 \text{ s} \]
\[ T_{G1} = T_{G2} = T_{G3} = T_{G4} = 0.08 \text{ s} \]
R₁ = R₂ = R₃ = R₄ = 2.4 Hz/p.u. MW
T₁₂ = 0.0866 p.u. MW/rad., ΔP₁₁ = 0.01 p.u.
D₁ = D₂ = 8.333 × 10⁻³ p.u. MW/Hz
B₁ = B₂ = 0.4249 p.u. MW/Hz, ΔP₁₂ = 0 p.u.
