Abstract—This paper presents the results of a study aimed at establishing the temperature distribution during the welding of magnesium alloy sheets by Pulsed Current Gas Tungsten Arc Welding (PCGTAW) and Constant Current Gas Tungsten Arc Welding (CCGTAW) processes. Pulsing of the GTAW welding current influences the dimensions and solidification rate of the fused zone, it also reduces the weld pool volume hence a narrower bead. In this investigation, the base metal considered was 2mm thin AZ 31B magnesium alloy, which is finding use in aircraft, automobile and high-speed train components. A finite element analysis was carried out using ANSYS, and the results of the FEA were compared with the experimental results. It is evident from this study that the finite element analysis using ANSYS can be effectively used to model PCGTAW process for finding temperature distribution.

Keywords—gas tungsten arc welding, pulsed current, finite element analysis, thermal analysis, magnesium alloy.

I. INTRODUCTION

WELD fusion zones typically exhibit coarse columnar grains because of the prevailing thermal conditions during weld metal solidification. This often results in inferior weld mechanical properties and poor resistance to hot cracking. While it is thus highly desirable to control solidification structure in welds, such control is often very difficult because of the higher temperatures and higher thermal gradients in welds in relation to castings and the epitaxial nature of the growth process. Nevertheless, several methods for refining weld fusion zones have been tried. Two relatively new techniques current pulsing and magnetic arc oscillation have gained popularity because of their striking promise and the relative ease with which these techniques can be applied to actual industrial situations with only minor modifications to the existing welding equipment [1].

Pulsed current welding, developed in 1950s, is a variation of constant current welding which involves cycling of the welding current from a high level to a low level at a selected regular frequency. The high level of the peak current is generally selected to give adequate penetration and bead contour, while the low level of the background current is set at a level sufficient to maintain a stable arc. This permits arc energy to be used efficiently to fuse a spot of controlled dimensions in a short time producing the weld as a series of overlapping nuggets and limits the wastage of heat by conduction into the adjacent parent material as in normal constant current welding. The technique has secured a niche for itself in specific applications such as in welding of root passes of tubes, and in welding thin sheets, where precise control over penetration and heat input are required to avoid burn through [2].

Current pulsing has been used by few investigators [3], [4], [5] to obtain grain refinement in weld fusion zones and improvement in weld mechanical properties. Most of the reported literatures have focused on pulsed current welding and their effects on mechanical and metallurgical properties and no literature is available on thermal analysis of PGTAW process. Hence, the present investigation has been carried out to understand the effect of pulsed current welding technique on temperature distribution in AZ 31B magnesium alloy using finite element analysis.

The basic theory of heat flow developed by Fourier and applied to moving heat sources by Rosenthal in the late 1930s is still the most popular analytical method for calculating the thermal history of welds. As many researchers have shown [6] – [9], Rosenthal’s analysis (which assumes a point, line, or plane source of heat) is subject to serious error for temperatures in or near the fusion and heat-affected zones. Since Rosenthal’s point or line models assume that the flux and temperature is infinite at the source, it would not account for the actual distribution of the heat in the arc and hence would not accurately predict temperatures near the arc. Later Pavelic [7] suggested that the heat source should be distributed and he proposed a Gaussian distribution of flux deposited on the surface of the work piece. Further John Goldak [9] proposed in his investigation a ‘double ellipsoid’ configuration of the heat source. Many other investigators have used this heat source model [10], [11]. The present investigation has been carried out to understand the effect of pulsed current welding technique on temperature distribution in AZ 31B magnesium alloy with the general purpose Finite

Element Analysis code ANSYS. The heat source model considered here is of the double ellipsoid configuration.

II. EXPERIMENTAL WORK

In this investigation, sheets of 2 mm thick were used as base material. The chemical composition and mechanical properties of base metal are presented in Table I. The sheets of magnesium alloy were cut to the required size (100 x 100 mm) by power hacksaw cutting and grinding. Square butt joint configuration was used to fabricate the welded joints. Single pass, autogenous welding procedure (without filler metal addition) was applied to fabricate the joints. High purity (99.99%) argon gas was used as shielding gas with a flow rate of 9 lpm. 2% thoriated tungsten electrode of 3.2 mm diameter was used with DC straight polarity (electrode –ve and weld plate +ve) to carry out the experiments. The arc length was maintained at 2mm.

The experimental setup is shown in figure 1. The Lincoln Electric GTA welding machine controlled the welding parameters, (model: “Precision TIG 375”). To measure the temperature during welding the K Type Chromel – Alumel thermocouple was used [12, 13, 14]. The hot end diameter of the thermocouple was 1.5 mm, the cold end was fixed to a thermocouple bank and this was in turn connected to the data acquisition system (DAQ) Labview. Labview was a bundled package on virtual instrumentation having the flexibility to measure the parameter of concern at very short interval. When used on Direct Current (DC) straight polarity Labview acquired data for both heating and cooling, but in Alternating Current (AC) configuration the DAQ could acquire data after the welding time, hence providing temperature history for the cooling. This being the limitation, the DC straight polarity was used for the investigation. Figure 2 shows the positions on the plate where the thermocouples were glued to a depth of 1mm, the holes were drilled at the bottom of the plate [15]. The data acquisition system of LABVIEW was used to acquire the temperature every second during weld from these 3 locations as well as the room temperature.

Before welding was performed, the sheets were cleaned and thermocouples were incorporated in its appropriate positions. Welding was done by both the constant current (CC) and the pulsed current (PC) process. A number of trial runs on the base material were performed to fix the upper and lower heat input levels. For the CC process higher than 262 J/mm (120 amps) resulted in burning of base metal and in PC process the burning happened above 263 J/mm (160 amps). The various penetration that was achieved during welding was compared. From the comparison the joint fabricated at 262J/mm (120 amps) in constant current had a penetration of 1.9 mm that was in parlance with the joint welded at 263J/mm (160 amps) of pulsed current whose penetration was 2.0 mm. The ratio of penetration to sheet thickness was 0.95 and 1 for constant current and pulsed current respectively. Both the joints had achieved full penetration. The ratio of width to penetration was 3.53 and 3.38 for constant current and pulsed current respectively. Hence these two joints exhibited similar physical characteristics and amenable for comparison as shown in table II.

The calculation of heat input (Q) for the pulsed current process was done by first computing the mean current using the relationship \( I_m = \frac{(I_p \times t_p) + (I_b \times t_b)}{t_T} \), where \( I_m \) is the mean current, \( I_p \) is the peak current, \( I_b \) is the base current, \( t_p \) is the time on peak pulse, \( t_b \) is the time on base current, and \( t_T \) is the total time [18]. From this, the RMS value of current or the effective current was computed and the heat input values obtained. For the calculation of the heat Input (Q) the relationship used for constant current process was \( Q = \frac{V \times I}{n} \eta \), where \( V \) is the voltage, \( I \) is the current, \( n \) is the welding speed and \( \eta \) is the efficiency of utilization of the heat generated [15] [18]. To calculate the heat input at peak and base current the above formula was used. The process parameter of these two joints is shown in table 3. For the modelling purpose the heat input was calculated for the peak current and the base current and presented in table III(a). [19] – [22]

### III. MODELLING DISCUSSION

An axisymmetric three-dimensional transient model is proposed with the general-purpose Finite Element Analysis code ANSYS. The governing equation for heat transfer in three dimensions arrived from the Helmholtz equation is

\[
\frac{\partial}{\partial x} \left( k_x \frac{\partial T}{\partial x} \right) + \frac{\partial}{\partial y} \left( k_y \frac{\partial T}{\partial y} \right) + \frac{\partial}{\partial z} \left( k_z \frac{\partial T}{\partial z} \right) + Q = 0
\]

where \( k_x \), \( k_y \), and \( k_z \) are the thermal conductivities in the \( x \), \( y \) and \( z \) directions and \( Q \) is the internal heat generation.

The derivation for the nodes and elements are done for the steady state conditions and transformed to the transient conditions. In the three dimensional analysis only conduction effects are included, the convection effects are treated most efficiently as boundary conditions.

The domain to which Equation 1 applies is represented by a mesh of finite elements in which the temperature distribution is discretized as

\[
T(x, y, z) = \sum_{i=1}^{N} N_i(x, y, z)T_i = [N][T]
\]

where \( N_i(x, y, z) \) is the interpolation function associated with nodal temperature \( T_i \), \([N]\) is the row matrix of interpolation functions, and \([T]\) is the column matrix (vector) of nodal temperatures, and \( M \) is the number of nodes per element. Application of the Galerkin method to Equation 1 results in \( M \) residual equations.

\[
\int \int \int \left[ \frac{\partial}{\partial x} (K_x \frac{\partial T}{\partial x}) + \frac{\partial}{\partial y} (K_y \frac{\partial T}{\partial y}) + \frac{\partial}{\partial z} (K_z \frac{\partial T}{\partial z}) + Q \right] dV = 0
\]

The volume integral formally gives the element stiffness matrix, where, \( i = 1, \ldots, M \) and \( V \) is element volume.

The derivative terms can be written as follows

\[
\frac{\partial}{\partial x}(K_x \frac{\partial}{\partial x} N_i) = \frac{\partial}{\partial x}(K_x \frac{\partial}{\partial x} N_i) - K_x \frac{\partial}{\partial x} \frac{\partial N_i}{\partial x} \frac{\partial}{\partial x}
\]

\[
\frac{\partial}{\partial y}(K_y \frac{\partial}{\partial y} N_i) = \frac{\partial}{\partial y}(K_y \frac{\partial}{\partial y} N_i) - K_y \frac{\partial}{\partial y} \frac{\partial N_i}{\partial y} \frac{\partial}{\partial y}
\]

\[
\frac{\partial}{\partial z}(K_z \frac{\partial}{\partial z} N_i) = \frac{\partial}{\partial z}(K_z \frac{\partial}{\partial z} N_i) - K_z \frac{\partial}{\partial z} \frac{\partial N_i}{\partial z} \frac{\partial}{\partial z}
\]

the residual equations become

\[
\int \left[ K_x \frac{\partial N_i}{\partial x} + K_y \frac{\partial N_i}{\partial y} + K_z \frac{\partial N_i}{\partial z} \right] A dV - \int q N_i dA = 0 \quad (i = 1, \ldots, M)
\]

Inserting the matrix form of Equation 2 and rearranging,

\[
\int \left[ K \frac{\partial N_i}{\partial x} + K \frac{\partial N_i}{\partial y} + K \frac{\partial N_i}{\partial z} \right] dV - \int q N_i dA = 0 \quad (i = 1, \ldots, M)
\]

Equation 7 is in the desired form is

\[
\left\{ T^{(v)} + [K^{(v)}] \right\} = \left\{ f^{(v)} \right\} + \left\{ f^{(v)} \right\}
\]

Comparing the last two equations, the element conductance (stiffness) matrix is

\[
[K'] = \int \left[ K_x \frac{\partial N_i}{\partial x} + K_y \frac{\partial N_i}{\partial y} + K_z \frac{\partial N_i}{\partial z} \right] dV
\]

The element nodal force vector associated with heat flux across the element surface area is

\[
\{f^{(v)}\} = \int \left\{ Q \right\}^T dA
\]

The model assembly procedure for a transient heat transfer problem is the same as for a steady-state problem, with the notable exception that the global capacitance matrix is to be assembled. Element nodes are assigned to global nodes and the element capacitance matrix terms are added to the appropriate global positions in the global capacitance matrix, as with the conductance matrix terms. The conditions for the transient state are derived out of steady state by the addition of the capacitance matrix. Thus for the element

\[
[C^{(v)}] \{T^{(v)}\} + [K^{(v)}] \{T^{(v)}\} = \{FQ\} + \{Fq\}
\]

where the gradient force vector \( \{Fq\} \) is composed of either unknown heat flux values to be determined or convection terms to be equilibrated with the flux at a boundary node.

The 3D element of “SOLID Brick 8 node 70” was chosen for the analysis. Half sheet was modelled since the other half would be symmetrical. Mapped meshing was used for the model, by defining the nodes. Finer meshing was done for the near weld zone while coarse meshing on the other areas. The aspect ratio for finer mesh was 5.99 and coarser mesh was 8.98, 11.98 & 14.97 – well below the limit of 20. The model for Pulsed current was designed based on the parameter of current [19] – [21] For a frequency of 6 hz, Pulse On Time 50% and for a speed of 4.167 mm/sec yielded

Number of Pulse per mm = 1.434
Time taken to traverse 1 mm – 0.239 Sec
Number of load steps per mm - 3
Time per Load step - 0.0797 Sec
Distance per Load step - 0.333 mm

The details of the model is presented in table 4
For the constant current, one load step for every 0.5 mm was considered and the time for each load step was 0.1195 secs.
The measured width of the weld is shown in table IV.

The temperature dependent Properties of thermal conductivity, specific heat and density were given as input.
Values shown in fig 3. Subroutines were written in APDL (ANSYS Parametric Design Language) using the DO loop and IF for the pulsing of heat input.

A. Boundary Conditions
In the case of three-dimensional heat transfer, four types of boundary conditions have to be specified: (a) specified temperatures, (b) specified heat flux, (c) convection conditions and (d) radiation conditions.
The first case, specified temperatures, is taken into account in the usual manner, by reducing the system equations by simply substituting the known nodal temperatures into the system equations. For the others the conditions are defined in zones. For the Zones :( as shown in fig 4)

$$H = 24.1 \times 10^{-4} \varepsilon \ T^{1.61} $$  \hspace{1cm} (17)

Where $E$ is the emissivity or degree of blackness of the surface of the body.

B. Heat Source Model

The ellipsoidal heat source model revealed that the temperature gradient in front of the heat source was not as steep as expected and the gentler gradient at the trailing edge of the molten pool was steeper than experimental measurements [9] – [11]. Hence two ellipsoidal sources were combined as shown in Figure 5. The front half of the source is the quadrant of one ellipsoidal source, and the rear half is the quadrant of another ellipsoid. The estimation of the heat input was made based on the equations 18 and 19 [11]:

\[ q_f = \frac{6\sqrt{3}Q_f}{\pi a b c} \exp \left(-3 \left[ \frac{x^2}{a^2} + \frac{y^2}{b^2} + \frac{z^2}{c^2} \right] \right) \]  \hspace{1cm} (18)  
\[ q_r = \frac{6\sqrt{3}Q_r}{\pi a b c} \exp \left(-3 \left[ \frac{x^2}{a^2} + \frac{y^2}{b^2} + \frac{z^2}{c^2} \right] \right) \]  \hspace{1cm} (19)

Where \( q_f \) and \( q_r \) are the frontal and rear fraction of the heat flux, \( a, b, c \) are the parametric values obtained from the metallographic data and from weld pool surface ripple markings as depicted in figure 5. \( Q \) is the calculated heat input.

The \( q_f \) and \( q_r \) values were given as input to the model by a subroutine created by the APDL.

C. Phase Change

To analyze the phase change problem, in the nonlinear transient thermal analysis the latent heat was accounted for (heat stored or released during a phase change). To account for latent heat, the enthalpy of the material as a function of temperature was defined. Hence the latent heat effect (accompanying change in phase from liquid to solid), is approximated by specifying a rapid variation in enthalpy over the “mushy” zone in a temperature range of \( \Delta T \). The enthalpy \( h \) variation is computed from equation 20 and given as input by the APDL subroutine.

\[ h = \int \rho c (T) \, dT \]  \hspace{1cm} (20)

IV. RESULTS AND DISCUSSION

A. Temperature Profile
The profile curves by the model showed a lower temperature compared to that of the experimental but was below 10% deviation. The difference in peak temperature between the process is 38 K but the heat input for the process is nearly the same, higher peak temperature is seen for the pulsed current. The reason for this can be attributed to the thermal conductivity of the base metal which varies from 515 to 550 W/mK in the temperature range of 450 to 500 K. Thereafter the thermal conductivity is more or less linear. During pulsing of the current the temperatures tend to fall below this range, hence to stabilize the temperature of the base metal, this phenomenon is noticed. The bead profile of the pulsed current were more controlled and the penetration was higher than the constant current. The cooling rate of pulsed current process was 8.2°C/second and that of constant current 5.5°C/second. It is seen that the cooling rate for pulsed current is much higher than that of the constant current.

B. **Prediction of Temperature at weld centre**

From the computed results, the temperature at the weld centre for both the pulsed and constant current was plotted. Figure 9 shows the values of the same. It is seen that when the peak temperature was reached there was not much of a difference between the constant current and pulsed current process.

V. **CONCLUSION**

From this investigation, it was found that

(i) The predicted values of temperature using the three dimensional FEA model are in good agreement with the experimental values.

(ii) The incorporation of the pulsing effect by providing two different heat inputs and the double ellipsoid model for the heat source has given realistic results with the phase change consideration.

(iii) A realistic prediction of the temperature at the weld centre was obtained.

ACKNOWLEDGMENT

The authors wish to express their sincere thanks to the, Department of Manufacturing Engineering, Annamalai University, Annamalai Nagar 608002 for the facilities provided to carry out this investigation.
