Fast and Efficient On-Chip Interconnection Modeling for High Speed VLSI Systems

A.R. Aswatha, T. Basavaraju, and S. Sandeep Kumar

Abstract—Timing driven physical design, synthesis, and optimization tools need efficient closed-form delay models for estimating the delay associated with each net in an integrated circuit (IC) design. The total number of nets in a modern IC design has increased dramatically and exceeded millions. Therefore efficient modeling of interconnection is needed for high speed IC’s. This paper presents closed-form expressions for RC and RLC interconnection trees in current mode signaling, which can be implemented in VLSI design tool. These analytical model expressions can be used for accurate calculation of delay after the design clock tree has been laid out and the design is fully routed. Evaluation of these analytical models is several orders of magnitude faster than simulation using SPICE.

Keywords—IC design, RC/RLC Interconnection, VLSI Systems.

I. INTRODUCTION

As the result of the scaling down of technology and increase in transistor density, the cross sectional area of wires has been reduced. With these trends, it is becoming crucial to be able to determine which nets within high speed VLSI circuit exhibit prominent inductive effects. To accomplish this, it is necessary to analyze and model the interconnects. An interconnection can be described by means of its electrical parameters, and today most extraction and delay analysis tools are limited to resistor and capacitance. The increasing operation speed of integrated circuits may have more important consequences on the transmission line. Therefore RC modeling is not efficient for global interconnection at high frequencies. Therefore, the model chosen to describe and simulate the interconnection should take effects of inductance into account. The most complete description of the line is given by the RLC model.

Various techniques have been proposed for the delay analysis of interconnects. These techniques are based on either simulation techniques or (closed-form) analytical formulas for voltage-mode (VM) signaling. Simulation tools such as SPICE give the most accurate insight into arbitrary interconnect structures but are computationally expensive. However, with the increasing speed requirements in VLSI circuits, current-mode (CM) signal transporting techniques may provide an attractive solution to some of the challenges caused by aggressive interconnect scaling.

The main objective of this paper is to find out when the inductance of the line must be included in the model considering a typical case of VLSI interconnections. The closed-form delay expression presented in this paper provides fast delay estimation including the inductance effect for long global interconnection. A closed-form RC model for CM interconnects has been derived using first order moment approximation. The RLC model is derived using the concept of absorbing inductance effect into equivalent RC model and then recurring MNA (modified nodal analysis) is used to obtain the equivalent resistance to model load delay.

The paper is organized as follows: section II presents the derivation of the closed form current mode (CM) delay expression for RC modeling; Section III presents the closed form CM delay expression for RLC modeling of interconnection. Section IV discusses the accuracy of RC/RLC delay formula in various operation regions.

II. CLOSED-FORM RC DELAY FORMULA FOR CM SIGNALING

Long global interconnects can be modeled by distributed RC transmission lines as long as the overall line resistance dominates the response (i.e.R>>jωL). The key to current-mode signal transporting is the low impedance termination at the receiver which results in reduced signal swings and increased bandwidth performance. The distributed RC model for CM interconnects [1] is shown in Fig 1a. The driver is modeled as a voltage source with source resistance Rs. For the sake of generality, the line is terminated with a resistor Rt and load capacitance Cl. For voltage-mode signaling the termination resistance Rt is infinite and the output voltage seen across Cl. In current-mode signaling, the terminating resistance Rt is finite.

![Fig. 1 (a) Generalized distributed RC model (b) Approximate effective lumped element model](image)

A. Effective Resistance and Capacitance

Since Elmore's formulation is basically a first moment approximation of the signal delay time, Moment-Matching Methods [2][3] can be used to derive a first-order RC network with effective lumped element parameters for voltage and current mode signaling. It is well understood that a lumped, linear, time-invariant circuit such as that of a generalized distributed RC line shown in Fig. 1, can be conveniently expressed in terms of state equations using the modified nodal
Analysis (MNA) representation [4]. The generalized output equation [1] can be expressed in the Laplace domain as:

\[ \bar{G} + s \bar{C} \cdot [X(s)] = b(s) \]  

(1)

where \( G \) and \( C \) are the nodal conductance and capacitance matrix, respectively; \( X(s) \) is the vector of node voltages; and \( b(s) \) is the input source excitation. The NxN nodal conductance matrix \( G \) for the circuit topology shown in Fig. 1(b) can be written as:

\[
\begin{bmatrix}
G_{o1} + G_o & -G_o & 0 & \ldots & 0 \\
-2G_o & -G_o & 0 & \ldots & 0 \\
0 & -2G_o & -G_o & \ldots & 0 \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
0 & 0 & -2G_o & -G_o & 0 \\
0 & \ldots & 0 & -G_o & G_k + G_o \\
\end{bmatrix} 
\]

(2)

\( G_o \) is the segment conductance of the distributed transmission line and \( G_k \) is the load conductance. In (2), \( G_{o1} = l/(R_S + R_L) \); where \( R_S \) is the source resistance and \( R_L \) is unit length resistance.

As described in [1][2], the node voltage vector \( X(s) \) is expanded using the Taylor series and coefficients of similar powers of \( s \) are equated to obtain the following expressions:

\[
GM_q = b 
\]

(3)

\[ GM_q = -CM_{q-1} \quad q>0 \]

There M, represents the moment vector of the transfer function \( H(s) \) of Fig. 1(a). A general closed-form expression for the \( q \)th moment and the \( k \)th node voltage of \( X(s) \) is given as:

\[
m_k^q = \sum_{j=1}^{N} -G_{mv}(k, j) C(j, \cdot) m_j^q
\]

(4)

where \( N \) is the number of distributed segments and \( G_{mv} \) is the inverse matrix \((G^{-1})\) which can be expressed as:

\[
G_{mv}(k, j) = \begin{cases} 
G_o + (N - k) G_L & j = k \\
\frac{G_o [G_o + (N - 1) G_L + G_k G_o]}{G_o [G_o + (N - 1) G_L + G_k G_o]} & j > k \\
\frac{G_o [G_o + (N - 1) G_L + G_k G_o]}{G_o [G_o + (N - 1) G_L + G_k G_o]} & j < k 
\end{cases}
\]

(5)

Similarly, we can express the \( 0 \)th moment for the \( k \)th nodal voltage as:

\[
m_k^0 = \frac{G_L G_o + (N - k) G_L}{G_o G_S + (N - 1) G_L + G_k G_o + G_L G_o}
\]

(6)

From (4), (5) and (6) all higher order moments can be derived.

To obtain the effective resistance and capacitance of the first order AWE approximation, we express the reduced single order rational transfer function \( H(s) \) in terms of the polynomial coefficients \( a_o \) and \( b_1 \), calculated from the \( 0 \)th and \( 1 \)st moments using (4) and (6), given as:

\[
a_o = m_o \quad b_1 = -m_1/m_o
\]

(7)

Since the pole of \( H(s) \) is \( l/(R_eff C_eff) \), the effective resistance and capacitance is derived from (7), which can be written in closed-form

\[
R_eff = \eta \cdot \frac{R_{tot}}{\sqrt{2}} \left( \frac{N+1}{N} \right) \left( 1 + \frac{R_{tot}}{3R_L} \left( \frac{N-1}{N} \right) \right) \\
+ 2 \eta \frac{R_S}{\sqrt{2}} \left( 1 + \frac{R_{tot}}{2R_L} \left( \frac{N-1}{N} \right) \right)
\]

(8a)

\[
C_eff = C_{tot} + \frac{R_{tot}}{R_eff}
\]

(8b)

\[
\eta = \frac{R_L}{R_L + R_S + R_{tot}}
\]

(8c)

Where \( R_{tot} \) and \( C_{tot} \) are the total resistance and capacitance calculated from the unit length components \( R_o \) and \( C_o \) and total interconnect length \( l \); \( N \) is the number of distributed segments; \( R_S \) and \( R_L \) are the source and load resistance respectively.

Thus the lumped element resistance and capacitance in (8) are the effective components that model the distributed transmission line. The generalized effective lumped element model is shown in Fig. 1(b). For current mode signals the source voltage \((V_P)\) is scaled by \( \eta \).

### III. CLOSED-FORM RLC DELAY FORMULA FOR CM SIGNALING

The distributed RLC model for CM interconnects [5] is shown in Fig. 2. \( R, L \) and \( C \) are designated as unit length resistance, inductance and capacitance, respectively. \( \Delta d \) is the length of each lumped section; \( R_L \) is source resistance; \( C_L, R_L \) are load capacitance and resistance. The principle of current mode signaling is that, by loading the line with finite impedance, the dominant pole of the system shifts, resulting which causes a smaller time constant and thus less delay.

**A. Absorbing Inductance into Effective Resistance**

In modern technology, as the self-inductance of the line increases, it affects both line delay and load delay. In order to quantify the inductance effect, a Voltage Mode delay model is expressed in terms of characteristic impedance \( Z_o \), which is derived using both analytical methods and simulation approximation in [6]. Fig. 3 shows the equivalent load delay for the VM interconnects [5], where \( Z_o = \sqrt{L/C} \), \( d \) is the total length of the line. As shown in Fig 3, in the case of RC model, the equivalent resistance is \( "R_o + R.d" \), in the case where inductive effect is considered the equivalent resistance is \( "R.o + 0.65 R_o + 0.36 Z_o" \), where the coefficient “0.65” and “0.36” reflect the shielding effect of inductance.
B. MNA for Closed-form Derivation

A long transmission line is a linear time invariant (LTI) distributed network that can be expressed in terms of state equations by using the Modified Nodal Analysis representation (MNA) [5][7], where G and C are the nodal conductance and capacitance matrices, respectively as shown in (9). X is vector of node voltages and b(s) is the input source excitation.

\[
\begin{bmatrix} G + sC \end{bmatrix} \begin{bmatrix} X(s) \end{bmatrix} = b(s)
\]

As described in part A, by absorbing the inductance effect into effective resistance, the inductance matrix is not included in (9) thus reducing the complexity; instead, the conductance matrix contains the inductance effect by replacing the unit length conductance \( G_u \) as shown below. \( G_o \) is equivalent source conductance and \( G_u \) the unit length conductance including inductance effect.

\[
\begin{bmatrix} G_o & G_u & -G_o & 0 & \ldots & 0 \\
-G_o & 2G_u & -G_u & 0 & \ldots & 0 \\
0 & -G_u & 2G_u & -G_u & \ldots & 0 \\
0 & \ldots & 0 & -G_u & G_o & G_u \\
\end{bmatrix}
\]

\([G] = \frac{1}{0.65R_o} \begin{bmatrix} G_o & G_u & -G_o & 0 & \ldots & 0 \\
-G_o & 2G_u & -G_u & 0 & \ldots & 0 \\
0 & -G_u & 2G_u & -G_u & \ldots & 0 \\
0 & \ldots & 0 & -G_u & G_o & G_u \\
\end{bmatrix} \]

The vector of node voltages of \( X \) is expanded into a Taylor series to obtain the moments \( M \) in (10), where the subscript of \( M_q \) indicates the order of the moments. By equating the moments of same order on both sides of (10), a final recursive relationship is obtained to derive the moment as shown in (11).

\[
\begin{bmatrix} G + sC \end{bmatrix} \begin{bmatrix} M_o + M_1s + M_2s^2 + \ldots \end{bmatrix} = b(s)
\]

\[
\begin{bmatrix} G \end{bmatrix} M_q = b
\]

\[
\begin{bmatrix} G \end{bmatrix} M_q = - \begin{bmatrix} C \end{bmatrix} M_{q-1} \quad q > 1
\]

From the 0\(^{th}\) and 1\(^{st}\) moments, the distributed network can be approximated into a 1\(^{st}\) order transfer function as shown in (12), where \( p \) is the dominant pole that determines the delay of the line.

\[
\hat{H}(s) = \frac{k}{s + p} = \frac{m_o}{s + m_0} \left( \frac{m_0}{m_1} \right)
\]

The denominator of the pole is organized into two parts in (13), the first term of the denominator represents the line delay; the second term represents the load delay. The expression in (13) can be still simplified by substituting for line and load delay components.

When inductance effect is dominant, the line delay can be expressed by the time of flight, \( t_f = d/\sqrt{LC} \), therefore the first term is replaced by \( t_f \) in final delay expression. The load delay is expressed as the product of \( C_L \) and the effective resistance of CM network in (14)

\[
C_L R_{eq,RLC} = C_L \left[ \frac{R_L}{1 + R_L / R_{eq}} \right]
\]

where \( R_{eq} = R_d + 0.65R_o + 0.36Z_o \).

Therefore the total delay is obtained as (15). Also, this result converges to voltage mode delay expression whose load resistance is infinite.

\[
t_{RLC,CM} = t_f + 0.693C_L \left( \frac{R_L}{1 + R_L / R_{eq}} \right)
\]

IV. METHODS TO FIND THE REGION OF OPERATION (RC AND RLC)

Identifying the nature of the line can help in predicting the accuracy of the expression. We develop a design guideline for the choice of the expression (RC/RLC) by observing the damping ratio of the line[5].

For CM signaling, a lumped system model can be used for the approximate evaluation of line inductance effect as shown in Fig. 4.

\[
\begin{bmatrix} G + sC \end{bmatrix} \begin{bmatrix} M_o + M_1s \end{bmatrix} = b(s)
\]

\[
\begin{bmatrix} G \end{bmatrix} M_q = - \begin{bmatrix} C \end{bmatrix} M_{q-1} \quad q > 1
\]

From the 0\(^{th}\) and 1\(^{st}\) moments, the distributed network can be approximated into a 1\(^{st}\) order transfer function as shown in (12), where \( p \) is the dominant pole that determines the delay of the line.

\[
\hat{H}(s) = \frac{k}{s + p} = \frac{m_o}{s + m_0} \left( \frac{m_0}{m_1} \right)
\]

The denominator of the pole is organized into two parts in (13), the first term of the denominator represents the line delay; the second term represents the load delay. The expression in (13) can be still simplified by substituting for line and load delay components.

When inductance effect is dominant, the line delay can be expressed by the time of flight, \( t_f = d/\sqrt{LC} \), therefore the first term is replaced by \( t_f \) in final delay expression. The load delay is expressed as the product of \( C_L \) and the effective resistance of CM network in (14)

\[
C_L R_{eff,RLC} = C_L \left[ \frac{R_L}{1 + R_L / R_{eq}} \right]
\]

where \( R_{eq} = R_d + 0.65R_o + 0.36Z_o \).

Therefore the total delay is obtained as (15). Also, this result converges to voltage mode delay expression whose load resistance is infinite.

\[
t_{RLC,CM} = t_f + 0.693C_L \left( \frac{R_L}{1 + R_L / R_{eq}} \right)
\]

The inductance effect in current mode can be evaluated using the system transfer function by pole-zero analysis in a
similar way in the voltage mode derivation [8]. The transfer function is in the form of
\[ H(s) = \omega_n \zeta \frac{s^2 + 2 \zeta \omega_n s + \omega_n^2}{s^2 + 2 \frac{d}{R_L} + R_i C_i \frac{s}{s + 1} + \frac{R}{R_L}} \]  

where \( \zeta \) is the damping ratio and \( \omega_n \) is the undamped natural frequency. \( H(s) \) is given by (16) and the damping ratio is given by (17).

\[
\zeta_{CM} = \frac{L d + R C_i}{2 R_L} \frac{1}{d L C_i \left(1 + \frac{R}{R_L}\right)}
\]

when \( \zeta > 1 \), the system operates predominantly in RC region; when \( \zeta < 1 \), the system will exhibit inductive effect; when \( \zeta < 0.7 \), the system enters inductance dominant region [9], where the RLC expression has the maximum accuracy.

Fig. 5 shows the delay versus load capacitance [5]. The damping ratio increases as \( C_i \) increases. When \( \zeta = 0.7 \), the expression has an error of 2% at point A where \( C_i = 350fF \). At point B, \( \zeta = 1 \), the accuracy of RLC model is equal to the RC model. As \( C_i \) increases further, the RC model becomes more accurate. Given the nature of the line, the designer can choose the appropriate model to estimate the delay.

Fig. 6 shows the comparison of HSPICE simulation with RLC and RC model. The 50% delay is based on step excitation versus line length
